SUPPLEMENT.

THE INDIAN MEDICAL YEAR, 1927.

A REVIEW.*

IN reviewing the Indian Medical Year, 1927, the reviewer would like once again to express his most grateful thanks to the numerous contributors who have helped to make this review a symposium by different writers, rather than a review by a single reviewer.

Undoubtedly, the most important medical event of the year in India was the very successful Seventh Congress of the Far Eastern Association of Tropical Medicine, held in Calcutta from December 5th to December 10th, 1927. This has been so fully dealt with in our columns elsewhere, however, that in the current article we shall only make occasional and passing references to it.

DISEASES OF THE TROPICS, EPIDEMIOLOGY, SYMPTOMATOLOGY, AND TREATMENT.

MALARIA.

The most interesting event of the year was the visit paid in January by Sir Ronald Ross to Malaya and Assam, and the opening by H. E. the Governor of Bengal on January 7th of the Ronald Ross Gate of Commemoration close to Sir Ronald's former laboratory at the Presidency General Hospital, Calcutta. A full account of this ceremony was given in our issue for March, and we are glad to say that a copy of this and of the photographs concerned has now been enshrined in the Wellcome Museum of Medical History. An account of Sir Ronald's visit to Malaya and Assam has subsequently been published by him, and was reviewed in our issue for December; the moral of it appears to be that it is the big commercial industries of India which are setting the lead to-day in malaria control, whilst municipalities and district boards tend to lag behind, chiefly for financial reasons. It is often said that India has made less use of the great discovery which Ross made within her borders than any other country; but this is simply not true; finances have been so stringent that more could not be accomplished. At the present time it would appear that the want of men is even more urgent than the want of funds, and that special efforts should be made to train up malariologists for the future needs of India. (At the same time it is amusing to reflect that the mosquitoes were especially troublesome and vicious in the *shamiana* which was erected for the opening ceremony at the Gate of Commemoration!)

We regret extremely the very serious illness which subsequently prevented Sir Ronald from coming out to India in December to the F. E. A. T. M. Congress as the guest of the Government of India, and trust that he will soon be restored to his customary vigorous health.

A still further event in connection with Sir Ronald Ross' great discovery has been the finding of certain missing letters in the Ross and Manson correspondence during the period of Ross' investigations, and their publication in our issue for August, as well as in other medical journals. These letters were found among the effects of the late Sir Patrick Manson.

Epidemiology and Prevention.—In this connection a large number of papers have to be dealt with. Perhaps the most interesting of all is the admirable memoir by Mr. Senior-White and Dr. Williamson in our issue for January, 1927, on the future of anti-malarial research. In reviewing this paper Col. Clayton Lane writes: 'It is quite impossible to give any adequate extract of this paper. It deals with the monetary benefits which must follow successful research. It emphasises the steps which led to the costly and unnecessary elevation of quinine to prominence among the cinchona alkaloids; to the need of local study of anopheles; to the cost of oiling and subsoil drainage.....; to the effect of peaty and mineralized waters on larvæ, which opens up an enormous field of investigation; to our great ignorance of the normal life processes of plasmodium and mosquito.....; to ignorance of the plankton food of mosquito larvæ of different species; and to many other matters of primary importance, if the malaria problem is to be solved. The paper is sure to be widely read and deeply studied.' The enthusiast is rare, the successful enthusiast still rarer. Enthusiasm by itself is blind, and imagination, penetration and sound inductive reasoning are required.

Dr. C. Strickland's malaria survey of the tea gardens of Assam has been completed, and the results published (in an abridged form) by the Indian Tea Association in a brochure which we hope shortly to review. In Assam, as elsewhere, each locality would appear to constitute a problem in itself; there is no royal and straightforward road to the extermination of malaria, and what suits one area may be quite unsuitable for another. The same author, with Dr. K. L. Chowdhury has published the results of an anopheline survey of Bengal—a paper which will be of interest to all public health workers in rural Bengal. Major G. Covell and Sub-assistant Surgeon J. D. Baily publish a report on a study of the malaria of the Andamans with special reference to the spleen rate. This constitutes a practical application in the field of Christophers' new and accurate method of estimating the true size of the enlarged spleen. The normal path of enlargement of the spleen in adults was found to correspond with that in children. In the case of both adults and children the percentage of parasite infections increases as the spleen enlarges. The gametocyte output (crescents) is not associated with immunisation, but the reverse. An unusually high prevalence of quartan malaria is noted in the Andamans, and is associated both with acute and chronic malaria. Finally, Sinton's method of enumeration of parasites by means of a standard suspension of the red blood corpuscles of the fowl was found to be convenient and easy of application under field conditions. The whole paper, in fact, consists of an application of recent and more exact methods to the study of malaria in the field.

Lieut.-Col. C. A. Gill contrasts his (sixth) annual forecast of malaria in the Punjab for the year 1926 with what actually happened. The method is based on the hypothesis that malaria epidemics are the outcome of a loss of equilibrium between infection and immunity, together with a study of the climatic factors concerned, especially of the rainfall during the earlier part of the monsoon, and the humidity index. Three districts, Jullundur, Ludhiana, and Hoshiarpur, were picked out as areas in which malaria was likely to become intense during the monsoon of 1926, and high epidemicity was also likely to occur in Sialkot and Amritsar. In general what actually happened tallied very closely with the forecast, but two discrepancies were noted; Lahore had much less malaria than was anticipated, and in Gujrat and Gujranwala an unexpected outbreak occurred in association with a rainfall which was definitely unfavourable to the occurrence of an epidemic; these latter areas need special investigation. A curious result of the publication of

---

* *Notes.*—(1) Unless otherwise mentioned, the commissioned officers referred to are all members of the Indian Medical Service. In order to save space, references to qualifications, appointments, titles and decorations have been omitted, except in a few instances.

(2) The reviewer has been much exercised in mind whether to include abbreviated references to the papers cited, or to append a bibliography, but has decided that to insert references would mar the continuity of the text, whilst to add a bibliography would make this supplement unduly long. The references concerned, however, have been filed, and we shall be glad to supply any enquirer with any special reference wanted.

(3) Extra copies of this supplement are available at Re. 1 each from Messrs. Thacker, Spink and Co., P. O. Box No. 54, Calcutta.

Col. Gill's forecasts has been that the *Statesman* of Calcutta has taken him to task, and considers that 'it is both unusual and wrong for health authorities to issue forecasts regarding the occurrence of epidemics as if they were crops or the monsoon.' We confess that we had not suspected the existence of 'fundamentalists' in the office of the most enlightened daily paper in India. If public health workers are not to be allowed to attempt the intelligent anticipation of epidemics and to take measures beforehand, we may as well abandon all attempts at preventive medicine in this country, and leave it to 'the sweet reasonableness of Nature' to kill off the excess population by famine and epidemic disease. Anyhow, the Meteorological and Agricultural Departments are allowed forecasts; so why not the Public Health Department?

From the United Provinces, Lieut.-Col. C. L. Dunn forwards the following notes on malaria in the provinces by Capt. D. Clyde, Assistant Director of Public Health (Malariology), U. P.

Anopheline mosquitoes in the United Provinces.—An investigation of the anopheline carriers in the United Provinces is being undertaken, specimens being sent in to the central laboratory by the Medical Officers of Health, District Medical Officers of Health and their assistants. All these medical officers possess a qualification in medicine and public health. It is obvious that this system of investigation is unlikely to yield results commensurate with the cost. The results cannot be taken as an indication of the officers' knowledge, but are probably due to the fact that the work of collecting mosquitoes is delegated to subordinates. Officers were requested to catch and despatch only adult anophelines and were asked to obtain these from different places in the municipalities and districts. Special attention was drawn to the fallacy that once an area was located where anophelines were plentiful, there was a tendency to send in large numbers of mosquitoes from that area and this resulted in an enormous number of *A. rossi* being sent in.

Results.

Total number of anophelines sent in.	Number of *A. rossi* among these.	Number of anophelines other than *rossi*.	Other insects sent in as anophelines (of which 75% were *Culex*).
21,897	21,405	492	16,452

The investigation is now carried out by sending out laboratory attendants who have been trained to eliminate *Culex* and *rossi* from their catches. Of the mosquitoes which they would discard as *A. rossi* a percentage is retained and sent in for examination so as to eliminate possible fallacies.

Species of anophelines in the United Provinces.—The following species of anophelines have been recorded up to date in the United Provinces. The number in brackets gives the number of districts out of 48 districts in the Province from which specimens have been recorded. The data is of necessity incomplete and is not based on uniform large catches in all districts:—

A. listoni (20), *A. culicifacies* (32), *A. willmori* (17), *A. maculatus* (16), *A. maculipalpis* (21), *A. stephensi* (22), *A. pulcherrimus* (4), *A. hyrcanus* var. *nigerrimus* (18), *A. barbirostris* (14), *A. subpictus* (25), *A. fuliginosus* (21), *A. minimus* var. *varuna* (2), *A. turkhudi* (3), *A. jamesii* (2), *A. lindesaii* (4), *A. gigas* (4).

Correlation of meteorological data and malaria.—It would appear from an attempt to work out the correlation between the statistics of districts (rural areas) over a period of years, and dealing with (1) average annual rainfall, (2) percentage of cultivated area irrigated by canals, (3) ratio of area under wet cultivation to total area under cultivation, and (4) deaths from malaria as a percentage of total deaths, that no definite correlation appears to exist and that the statistics under each head are liable to such great errors that they would render any standard factor of correlation useless in any case.

Bhim Tal malarial survey.—A malarial survey of Bhim Tal was performed in May and June 1913 and October 1913 by Major Graham, I.M.S., and certain anti-malarial measures were carried out subsequent to this. A survey of the area was again carried out in May and June 1927 and is being reported upon in detail, but from this the following results appear:—

(1) Malaria has increased in Bhim Tal.

(2) The increase is chiefly due to the fact that the network of *kutcha* drains in the low lying grounds to the north of the lake are improperly kept and have become excellent breeding grounds. The larvæ from this area alone bred out into *A. listoni*, *A. willmori*, *A. maculipalpis*, *A. maculatus* and *A. fuliginosus*.

Kashipur malarial survey.—Malarial surveys of several areas in the U. P. Terai have in previous years been carried out and a malarial survey of the Kashipur Tahsil of the Terai and Bhabar was carried out in March, April and May 1927, with a view to determining the cause of the decrease in population in this area. The population has decreased from 71,412 in 1872 to approximately 35,000 in 1927. The average birth-rate for 46 years was 35.99 and the average annual death-rate 45.30. The provincial death-rate for this period was 35.23 and the provincial birth-rate 39.38 per mille.

The survey included 83 villages in a greatly depopulated and waste area of 189 sq. miles. Taking only the rural area figures and excluding the results of the surveys of the towns, out of 1,756 children between 2 and 10 years of age examined (excluding sick children) the splenic index was 49.88 per cent. Out of 1,136 blood slides from these children 18.92 per cent. showed malarial parasites of which 73.4 per cent. were M. T., 22.9 per cent. B. T., 1 per cent. quartan, and 2.7 per cent. mixed infections.

The anopheline mosquitoes found were *A. fuliginosus*, *A. listoni*, *A. maculipalpis* var. *indiensis*, *A. maculatus* var. *dravidicus*, *A. culicifacies*, *A. hyrcanus* var. *nigerrimus*.

No oöcysts or sporozoites were found in 270 anophelines examined. (Approximately equal numbers of *A. listoni*, *culicifacies* and *maculatus* were dissected.)

After allowing as far as possible for the fallacies in the statistics (which are available for a period of 46 years) and correlating the survey work done, it is estimated that approximately 60 per cent. of all deaths in the Tahsil are due to malaria. Only 5 per cent. of the villages were found to be healthy (spleen rate under 10 per cent.); 14.4 per cent. were found to be moderately endemic; 18.0 per cent. were highly endemic, 62 per cent. were hyper-endemic.

Leaving out the tract where malaria is due to natural conditions such as the proximity of breeding-places in the ravines and jungle to habitations, by far the greatest if not the only factor of importance is the system of *guls* from the canals which account for the breeding-places of all the carrier anophelines found. The rise and fall in the population of Terai villages would appear to be to a great extent due to a vicious circle: decline commences with some deaths in the malignant malaria season, over-irrigation of the fields becomes more and more marked as the population decreases and the water is allowed to flow over the now uncultivated areas, malaria increases until ultimately the village is deserted by the remaining inhabitants. After a period of years settlers again come and begin by re-digging the old *kutcha guls* thus bringing malaria up to the *abadi*. Whether they also desert the area or die, or the village again becomes prosperous depends on the excess or scarcity of the irrigation water. Cultivation only means no malaria in as far as it means no waste or excess or irrigation. The remedy for this tract of the Tahsil would appear simply to be the fitting of regulators on the outlets from the canals and controlling the irrigation carefully.

Immunity among Tharus and Bhuksas.—It is pointed out that the Terai tribes of Tharus and Bhuksas who have been stated to have a relative immunity to malaria as long as they remain in the infected area but die on their return to the area after emigration, live as a rule in thin-walled dwellings as against the thickly-walled

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

huts of other cultivators, that a large diurnal variation of temperature exists over the whole area where the tribe is found, that they are wealthier and possess more cattle than the indigenous cultivator and tend to keep their cattle in byres surrounding, and at some distance from the village huts, that adult carrier anophelines are seldom found in houses but in large numbers in byres, that the splenic index under 10 years of age among Bhuksas is not notably less than among other classes and that the splenic index above the age of 10 years is much less than in other cultivators of corresponding age periods. Another difference is that Bhuksas and Tharus eat fish as a staple article of diet and consume alcohol.

Dr. S. L. Hora, D.SC., of the Zoological Survey, pleads for an increased use of mosquito larva eating fish, and for closer co-operation between the Public Health and Zoological Departments. The only Fishery Department in India which now deals with this problem is that in Madras, but even here there is but little demand for larvicidal fish. The available literature on the Indian species of fish concerned is cited, and instances given of the value of fish control. A comment is also made on the bad habit of the Fishery Departments in introducing into tanks larger predaceous fish which prey on the larvicidal species. S. L. Sarcar gives an interesting account of an ancient flush and flood scheme in connection with the ancient ruined city of Gour in the Malda District. In 1922 the inhabitants in a part of this area surreptitiously cut the *bunds* which controlled the rivers, and flooded their lands in order to grow paddy; the result has been a steady diminution of malaria in the flooded areas. M. V. Perumal records cases of indigenous cases of malaria occurring at the high altitude of Coonoor, 5,500 to 6,000 feet, a dhoby ghat in a valley in the station being apparently chiefly responsible for the carrying of anophelines. Lieut.-Col. L. Reynolds has a useful note (*R. A. M. C. Jl.*, Vol. 48, p. 302) on a method of erecting mosquito nets at very cheap cost by means of wiring in hospital wards and barracks—a method which we understand is now coming into general use in Indian military hospitals.

Only a few of the published papers of the year deal with the *symptomatology* of malaria. With regard to *diagnosis* Dr. Neave Kingsbury reports on a study of the complement fixation reaction.

"None of the complement fixation tests employed for such chronic affections as tuberculosis, hydatid disease and schistosomiasis have proved comparable with the Wassermann reaction, but, by reducing the dose of complement to a minimum and by employing a suitable antigen, some success has been obtained. In such conditions the efficacy of the test centres round the discovery of a sensitive and highly specific antigen of low anti-complementary power. Eleven antigens were tested, eight from the spleen, liver, heart, brain and blood of a subtertian infected patient who died comatose after a single quinine injection, and three from the blood of one, 1|16th of whose corpuscles were infected with *P. vivax*. The most satisfactory antigens were saline emulsions of washed and lysed blood. The results these gave were as follows. Of subtertian malarias, 25 were tested with *P. falciparum* antigen and 48 per cent. were positive (graded as 1 to 4); while 16 were tested with *P. vivax* antigen with 31 per cent. positive. Again, of tertian malarias, 12 were tested with *P. falciparum* antigen with 50 per cent. positive, and six with *P. vivax* antigen with 67 per cent. positive."

Treatment.—Major J. A. Sinton has continued his studies in the treatment of malaria. In conjunction with Major W. Bird, R.A.M.C. and Assistant Surgeon S. N. Eate, I.M.D., he finds Peracrina of little or no value. 'Even if Peracrina 303 has a beneficial effect in chronic malaria, the cost, the length of treatment required and its uncertainty make it unsuitable for routine use as compared with quinine. Twenty-five cases of chronic benign tertian malaria were treated by intravenous injections of sodium stovarsol, varying doses up to a total of 4 grms. being given in five days. The intravenous injection of 1 grm. will cause the temporary disappearance of *P. vivax* from the peripheral blood and a 'clinical cure' in the majority of cases, but there is only a very small percentage of true cures, and the drug has not as rapid an effect in reducing the size of the enlarged spleen as have the cinchona alkaloids. Further, the primary injection of sodium stovarsol may have a provocative action and produce febrile symptoms in an afebrile patient, whilst toxic symptoms may follow the administration of the drug. Whilst it may have a limited value in the rare cases where the cinchona alkaloids cannot be tolerated, its rôle is markedly inferior to theirs.'

Lieut.-Col. A. H. Proctor deals with the 'treatment' of malaria as carried out in *mofussil* dispensaries in this country. A patient who does not bring a bottle for medicine with him only gets one dose of quinine, and even a patient who brings a bottle only receives three doses. He estimates that 92 per cent. of malaria patients attending dispensaries do not receive sufficient quinine to cure their fever, and this especially tends to bring 'Western' medicine into disrepute. In one dispensary investigated it would have cost Rs. 720 per annum to give every malaria case 90 grains of quinine; the total actual annual allotment for dressings, instruments, and drugs was Rs. 500, of which Rs. 288 per annum was expended on quinine. How is this state of affairs to be remedied, he enquires; the answer is not easy.

An interesting correspondence has taken place in the *British Medical Journal* on 'quinine resistance' in malaria. 'I.M.S.,' writing from the Punjab, and clearly with a very large experience, notes that in practically all unyielding cases the urine showed no quinine, in other words the quinine prescribed had either not been taken or had not been absorbed. These cases at once yielded to quinine when administered under strict supervision. There appears to be evidence that the hydrochloride or bi-hydrochloride is much better absorbed than the relatively less soluble sulphate.

Col. F. de Mello, Director of the Medical Services, Nova Goa, with H. M. P. Vernecar report that they have found Smalarina (Cremonese) to be useless in the treatment of malaria. In six cases treated as far as possible the full treatment of 120 tablets in 30 days was adopted. Nausea, vertigo, and even vomiting and headache resulted, and the drug was of no value, quinine and arsenic having to be given afterwards.

Several papers published in India during the year deal with Plasmochin. The most important is that by Dr. W. Fletcher and K. Kanagaraver, D.T.M. (Bengal) from the Institute for Medical Research, Kuala Lumpur, F. M. S., published in our issue for September. In all these workers treated 97 patients who were throughout under close supervision in hospital, blood films being examined daily. Of these 46 were cases of benign tertian malaria, and in these parasites disappeared in every case, except one, on the fourth day of treatment. In 10 cases of quartan malaria treated parasites all disappeared by the fifth day of treatment. In sub-tertian malaria (29 cases) the results were disappointing, but the manufacturers themselves emphasize the necessity in such cases of combining quinine with the plasmochin therapy, and their claim that plasmochin has a direct lethal effect on the gametocytes of *P. falciparum* was well borne out in the series, no crescents being seen after the seventh day of treatment. Further, the drug is tasteless, and is easily taken. On the other hand it is not always free from toxic symptoms, and these authors consider that its administration should be confined to hospital patients who are under full observation. Several cases of relapse were seen after plasmochin treatment, but the conditions of the experimental trial were such that it was impossible to compare the incidence of relapses after plasmochin treatment with that after quinine treatment. On the whole, it may be said that plasmochin is a valuable secondary line of treatment in malaria, but it does not appear to be of equal value to the standard quinine treatment; perhaps it represents a big step forward towards the ideal of a drug which will efficiently and rapidly cure malaria in a few doses only.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Drs. B. G. Vad and G. B. Mohile of the Sir J. J. Hospital, Bombay, on the other hand, are loud in their praise of plasmochin. After treating 16 cases they are of opinion that the blood is completely sterilised of parasites in from 24 to 48 hours; that it has a specially marked parasiticidal effect on the crescentic gametocytes of *P. falciparum;* and that 'the days of quinine are numbered.' 'Plasmochin is for malaria what Bayer 205 is for trypanosomiasis.' On the other hand, D. K. L. Basu Mallik is much less confident of the non-toxicity of plasmochin, and draws attention to the report of a death following its use in the annual report for 1926 of the United Fruit Co., U. S. A.

A special feature of the year 1927 with reference to malaria in India has been the number of special *publications* dealing with this subject. Priority of place must be given to the sumptuous memoir on *Malaria in India* by Major-General Sir Patrick Hehir, I.M.S. (retd.), published by the Oxford University Press, and recently reviewed in our columns. This is a compilation which includes information on every possible aspect of malaria in India culled from a thousand and one different sources, and splendidly illustrated. A second but less ambitious book is Knowles and Senior-White's *Malaria in India, its investigation and control, with special reference to Indian conditions.* This represents an attempt to put together into compact and yet fully illustrated form the information required by field and laboratory workers on malaria and malaria survey work. It has been favourably reviewed on the whole; the *Journal of Tropical Medicine and Hygiene*, the *Bulletin of Hygiene*, *Nature*, the *Lancet*, and the *Journal of the Royal Army Medical Corps*, amongst other journals, have been very favourable. On the other hand the chief criticism passed—especially by the *Bulletin of Entomological Research* and by the reviewer in the *Pioneer*—has been that the book contains very little original matter. This criticism, which is perhaps not altogether a legitimate one, rather misses the point; the book was not intended to present original and research matter, but to serve as a vade-mecum for field workers, and to summarise in compact from knowledge which has already accumulated.

Other publications during the year reflect the renewed activity of the Central Malaria Organisation under the Indian Research Fund Association at Delhi. These include first a very valuable memoir by Major G. Covell on the distribution of the anopheline mosquitoes of India and Ceylon. In reviewing this monumental work, Col. Alcock writes, 'the less showy part of the work must have demanded an infinite amount of toil—labour of the kind that brings its physic only to the man of inflexible resolve.' It represents, in brief, a standard work of reference for all malariologists in India and Asia, most carefully compiled, and very finely illustrated. Still another of the *Indian Medical Research Memoirs* (No. VII) by the same author is a critical review of the data regarding the transmission of malaria by the different species of *Anopheles;* with notes on their distribution, habits, and breeding-places. Again, Major Covell has placed the whole medical profession and public health services of the country under a great debt of obligation to him for this careful, detailed, well-indexed, and copious review; it forms a foundation with regard to what is already known—a foundation on which investigators of the future will build; not the least welcome feature of it is its extensive bibliography. It is work well worth doing, and well executed.

A further publication of the year in India is the *Synoptic Table for the Identification of the Anopheline Mosquitoes of India* by Col. S. R. Christophers, F.R.S., Major J. A. Sinton, and Major G. Covell, published by the Government of India, Central Publication Branch. 'This useful key,' writes Col. Alcock, 'is well lubricated with explanatory notes, definitions of topical terms, and figures of specific features.' A still further publication of the year is Dr. C. Strickland's illustrated key to the identification of the anopheline larvæ of India, Ceylon, and Malaya, which has also been favourably reviewed by Col. A. Alcock. He writes 'this excellent book, the doctrine of which is that for the medical man and sanitarian, the identification of anopheles larvæ in the field is a great economy, contains besides the means of identifying them, a canon and complete ritual of the science and art of manipulating anopheles larvæ ..... also there is for workers situated in the Orient a series of keys, all of simple construction and plainly illustrated by enlarged drawings, by which the larvæ of the species of *Anopheles* inhabiting India, Ceylon, and Malaya can be identified severally.'

Finally, a publication of special value is Dr. H. F. Carter's monograph on malaria and anopheline mosquitoes in Ceylon. This has been reviewed at length by Dr. P. A. Buxton, Entomologist to the London School of Tropical Medicine, in the January 1928 issue of the *Tropical Diseases Bulletin*. The original paper is so detailed, so splendidly illustrated, and so comprehensive that it defies analysis. The effects of altitude and rainfall become especially apparent in this report, also of local irrigation and the reverse. The report is of very great value to all malariologists, and we can only refer them to it in the original.

B. S. Chalam, who is in charge of the anti-malarial measures in connection with the Back Bay Reclamation Scheme, Bombay, reports on the possibilities of Paris green as an anopheline larvicide, his article being illustrated by drawings of the different apparatus used. He concludes that Paris green deserves much more attention as a larvicide than it has hitherto received in India. Its cheapness, effectiveness—even in the presence of thick vegetation—and its simplicity of application are entirely in its favour. It is a pure larvicide, however, and has no action on *Culex* larvæ or on the eggs and pupæ of *Anopheles*. As long as one keeps to windward of the spray Paris green has no toxic action on the persons using it as a spray.

* * * * * * *

Perhaps we have paid special attention in this year's review to malaria, but, after all, it is the most important disease of the tropics. And from every source, whether official or non-official, we gather a general impression that India is now very fully alive to the vast importance of this disease in her general mortality, and still more in her general morbidity. Money has been tight of recent years—admittedly, but the finance departments are now more inclined to be generous. What we now want are the *men*, and where they are coming from one cannot at the moment see. However, there are big organisations either in being in course of development, or in embryo. And, if one may attempt to summarise the present state of affairs, it would be to remark that the present methods of malaria control are too expensive for so poor a country as India. But there may be other, cheaper, more effective, biological methods; we need two things especially, the further prosecution of research, and the further application in our present-day public health policy of the results already achieved by previous research work.

In connection with *blackwater fever* Lieut. T. W. Twells, I.M.D., reports an interesting case. The patient was a European male missionary with previous Army service in Mhow and Nowshera, and he had also visited the hill stations in South India and Mussoorie. He had been in India for only six years, was aged 25, and had never had any sign of malaria. In 1926 when at Roorkee near Poona he suddenly contracted blackwater fever, with *P. falciparum* present in his blood films. He had never taken prophylactic quinine and this was apparently his first infection in India with malaria. Under cautious quinine therapy the condition of blackwater cleared up, and the patient was subsequently invalided out of India. The author asks for information with regard to similar case-histories of 'first attacks.'

PLAGUE.

Epidemiology.—Perhaps the most important publications of the year are the two papers by Dr. Fabian Hirst of Ceylon, summarising his well-known work of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

several years on the epidemiology of plague as studied in Colombo; also his further paper, which is largely a review of that work, read before the Royal Society of Tropical Medicine and Hygiene. In 1913 Hirst discovered that *Xenopsylla astia* was the sole rat flea of the two principal plague-free cities of the Orient, Madras and Colombo. He considers that *X. cheopis* was introduced into Colombo in 1914, and has only to be introduced into Madras for plague to become endemic there. Plague is not merely a disease of rats and man; it is also a disease of the transmitting flea, whose proventriculus becomes blocked with a solid growth of *B. pestis*, so that the flea cannot feed again until this plug has been ejected. The vitality of plague-blocked *astia* appears to be definitely lower than that of *cheopis* under similar conditions, and its mortality rate greater; hence it is a vector of low efficiency. *X. astia* can transmit however when climatic conditions are favourable to it; and Hirst concludes his first paper by a consideration of the possibility of forecasting plague epidemics in any given area. In his second memoir, Hirst discusses the geographical range and evolutionary history of the different species of rat fleas. The ancestral home of *X. cheopis* was probably the Nile valley, and the incidence of bubonic plague is in general terms greatest where climatic or other conditions especially favour *X. cheopis*. *X. astia* is characteristically a Southern Asiatic species; and the different geographical distribution of the two species is not so much attributable to climatic factors as to zoogeographical ones. When plague first broke out in Colombo the proportion of septicæmic (i.e., non-bubonic) cases seen was high, and the possibility of such cases when transferred to other areas acting as new foci of infection is discussed. Lately, however, the majority of cases have been of bubonic type and less infectivity. Grain containing infected fleas is the greatest source of danger in Colombo, and he concludes 'the prevention of the spread of plague is a problem in applied biology, depending for its solution on an exact and comprehensive study of local conditions and a catholic understanding of the intricate and ever varying relationships between the virus of the disease, the cold-blooded arthropod vector, and its warm-blooded mammalian host.' In general, he concludes that the failure of plague to spread in Europe during the present pandemic is probably due to a retrogression in the area infected by *X. cheopis* just as the appearance of bubonic plague in recent times in Ceylon, Australia, Japan and America is due to the widespread extension of this area by means of rapid transport.

With regard to the United Provinces Col. Dunn sends us the following note:—

The Indian Research Fund Association made a grant of Rs. 20,000 in 1926 for an enquiry into the experimental transmission of plague. Dr. A. N. Goyle, M.B., PH.D., was deputed to undertake this investigation. He has carried out a large number of comparative transmission experiments with *X. cheopis* and *X. astia* which lend support to the view that *X. astia* is a less efficient vector of plague than *X. cheopis*. For example out of fifty-two experiments with susceptible rats in which *X. cheopis* was used a successful transmission occurred in twenty-five, while under exactly the same conditions, nine out of fifty-two experiments with *astia* were successful. Continuous and successive transmission was obtained with eight rats in the *cheopis* cage and with only two in the *astia* cage. The results of both the series of experiments demonstrate the superior efficiency of *X. cheopis* as a vector of plague compared to *X. astia*. An interesting point which emerges from this study is that males of both *X. cheopis* and *X. astia* appear to transmit plague to rats more readily than the respective females of these two species. Evidence has been obtained to show that a rise in saturation deficiency exerts an unequal effect on the plague transmitting power of *X. cheopis* and *X. astia*. It was found for example, that *cheopis* failed to transmit plague at a temperature of 68°F. when the saturation deficiency rose to 0.6 of an inch, whereas at the same temperature *astia* did not carry plague beyond a saturation deficiency of 0.3 of an inch. It is suggested that the flea-species is a factor of considerable importance, though not the only factor involved in the spread of plague, and that the presence of *astia* to the exclusion of all other fleas over a large tract of the country may account for its immunity from plague. The longevity of fleas apart from their host has been shown to depend principally on the drying power of the atmosphere. The males of both the species have a shorter duration of life than their respective females. *X. cheopis* lives longer than *X. astia*.

"Liverpool Virus," which was first introduced by Professor H. E. Annett of Liverpool some 22 years ago and is now manufactured by Messrs. Evans Sons, Lascher and Webb, Ltd., Liverpool, was made the subject of experiment on Lucknow rats. The results obtained do not justify its use in the destruction of rats on a large scale, for out of forty-three rats fed with a varying amount of the virus only eight died within two to seven days and four rats died within eight to ten days. The remaining thirty-one rats were found to be healthy. The label on the tins containing the virus states that "it takes about a week for the rodents to die off." The special plague enquiry at the Haffkine Institute under the Indian Research Fund Association was continued during the year. Dr. B. P. B. Naidu and Jemadar Shamsher Jang, I.M.D., describe successive improvements effected in the constitution of the broth used for Haffkine's prophylactic plague vaccine preparation; the pH values for maximal growth were from 6.6 to 7.0, and the most favourable immunity was shown by rats inoculated with vaccine made from broth with an initial pH value of 6.8. The same authors have studied the production of alkalinity by *B. pestis* in broth cultures; during growth the alkalinity of the culture steadily rises, and reaches a maximum between the fifth and eleventh week of incubation; after an incubation period of 176 days the organisms are still viable and give good sub-cultures on agar slopes. The amount of alkalinity present in the vaccine has apparently no influence either on its toxicity or on its potency as estimated in rats.

Turning to *symptomatology and treatment*, Khan Bahadur Dr. N. H. Choksy has a very interesting account of the pathology of plague, based on his many years experience at the Mahratta Hospital, Bombay. He divides the cases seen into the bubonic type, the septicæmia type, the pneumonic type, and the cellulo-cutaneous type. This last type, he claims, has been overlooked. He concludes that attempts to tinker with one or other drug in the treatment of plague are useless; what is wanted is an efficient anti-serum of high titre. The Rev. Father J. F. Caius, Dr. Naidu, and Shamsher Jang from Parel report on an investigation into the bactericidal action of the commoner phenols and their derivatives *in vitro* on the *B. pestis*. These compounds are relatively insoluble in water, but are soluble in alkalies, and solution in an alkaline medium may either depress or intensify their bactericidal action. Those which were found to be the most active were quinol, mercurochrome, catechol, alpha-nitroso-beta-naphthol, toluhydroquinone, minophenol, carvacrol, and trichlorphenol. Father Caius, Dr. S. A. Kamat, and Dr. Naidu have further investigated the bactericidal action of organic derivatives of mercury on *B. pestis*, testing the action of mercurial derivatives of phenol, trypan red, trypan blue, and acid fuchsine by their so-called 'inhibitory method.' The aromatic mercurials were found to be many more times as active as the compounds from which they were derived. In general the bactericidal power is proportional to the amount of mercury present, and but little change is brought about by modification in the chemical constitution.

R. D. Pal pleads for the much more extensive use of anti-plague serum. Using the serum obtained from the Institute Pasteur, Paris, he gives doses of from 40 to 60 c.c. intravenously morning and evening until the temperature drops to normal. Each injection is followed by a marked increase in the patient's comfort; adrenalin is also given hypodermically, and a stimulant mixture containing ammonium carbonate and digifortis

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(P. D. & Co.) orally. Local treatment of the buboes is of little use, except for hot fomentations, and incision when suppuration has occurred. A small hypodermic dose of morphia with atropine is of real value, giving the patient sleep and a good night, and conserving his powers. A. S. Dawson also strongly advocates the intravenous use of anti-plague serum, giving doses of from 30 to 40 c.c. intravenously with a further 20 to 60 c.c. into the cellular tissues of the abdominal wall or thigh. In many cases the measure appears to have saved life, and in some the most dramatic change for the better was evident within 24 hours. He also administers a mixture containing adrenalin, digitalis, and aromatic ammonia by the mouth.

It seems to be increasingly clear that a really efficient anti-plague serum is badly wanted in India, if it can be manufactured, and we are glad to note that the Indian Research Fund Association have taken up this problem.

From the Haffkine Institute, Parel, Col. Mackie writes as follows:—

Dr. B. P. B. Naidu and Jemadar S. S. Jang, I.M.D., have been experimenting on the production of a potent anti-plague serum. By immunising rabbits with intravenous injections of virulent cultures isolated from the heart blood of plague rats they have succeeded in obtaining a serum of very high agglutinating titre, and the experiments so far carried out show that this serum has very potent curative properties. They find it possible to save an infected rabbit from death even when the serum is administered on the fourth and fifth day of infection.

These workers have also tested the therapeutic value of mercurated trypan blue on twelve rabbits experimentally infected with plague and found it to be of no value. They selected this compound out of 32 mercurated compounds of trypan blue, trypan red and fuchsin by studying their antiseptic action on *B. pestis* and their toxicity to animals.

Dr. Naidu has also continued his enquiry on Haffkine's prophylactic on the lines indicated by him last year.

Bacteriophage.—Dr. C. R. Avari has been engaged on the isolation of bacteriophage for different pathogenic organisms.

After several attempts he has succeeded in isolating a powerful strain of "phage" for *B. pestis*. The preventive and curative value of this phage is being studied. He has also isolated strong strains of phage for dysentery organisms (Shiga and Flexner), for *B. coli*, for *B. pyocyaneus*, and for the gonococcus.

CHOLERA.

Epidemiology.—Most of the published papers of the year deal with this aspect of cholera. Lieut.-Col. F. J. Palmer, R.A.M.C. (retd.), believes that Koch's vibrio is not the true ætiological agent of cholera, but that a cocco-bacillus, which often shows bipolar staining appears to be responsible, at least in Cachar. This may or may not have some association with a small spore-bearing bacillus which is often present, whilst the pig which is so ubiquitous on the tea estates in that area may have something to do with the spread of cholera. We fear, however, that bacteriologists will fail to agree with him.

The question which, as usual, has attracted most attention during the year is the perennial one of the relationship of the true (agglutinable) vibrio of Koch to the morphologically similar non-agglutinable vibrios so commonly found in fæces and in water supplies during cholera epidemics and in the endemic cholera areas. Dr. B. B. Brahmachari of the Bengal Public Health Department claims that non-agglutinable vibrios can be converted into the true agglutinable Koch's vibrio, chiefly by passage through rabbits and on repeated subculture on media: they meantime lose their agglutinability to their own specific homologous serum. This is a very big claim, and if further work confirms it, it marks a very big step forward in our study of cholera. The reverse process—the loss of agglutinability by strains of Koch's vibrio—is a well known phenomenon, but if non-agglutinable vibrios can be really proved to be but mutations of the true Koch's vibrio, then they assume a new importance in connection with the ætiology of the disease; the tendency hitherto has been to regard these non-agglutinable strains as rather degenerated and non-infectious strains of the true vibrio of cholera. The same author has also carried out an extensive series of observations in connection with the carrier question in Bengal. The stools of over 4,800 persons in the endemic areas were cultured, and the total carrier percentage turned out to be only 0.5 per cent.; 6 convalescents or contacts yielded agglutinating vibrios, and 23 vibrios of non-agglutinating type. In a further series of observations in villages near Calcutta 0.4 per cent. of persons examined were true cholera carriers, but no less than 13.7 per cent. yielded non-agglutinating vibrios. The number of examinations upon which these conclusions are based is very large, and the relationship of the non-agglutinating to the agglutinating strains again comes up for consideration. Can seasonal or other factors convert one strain into the other? or passage through the intestinal tract of a suitable person?

In our issue for February, Dr. J. W. Tomb and Capt. G. C. Maitra summarise the results in general of their well known work on cholera under the title 'A new conception of the epidemiology and endemiology of cholera.' Their work is based upon their 'open-bowl' method of cultivating stools, which yields a far larger percentage of positive findings of vibrios than other methods. In the Asansol Mining Settlement from November to February during the cold weather they find that vibrios are so scarce in the water of the ground tanks universally used for bathing and drinking as to be practically negligible. With the onset of the hot weather in March they begin to appear and become very numerous as the season advances, and the brief thunderstorms of that period seem to very greatly increase their prevalence by washing infective material from the sides of the tanks into the water. With the onset of true monsoon conditions, however, in July the vibrionic content again drops. The curve for vibrionic content of these tanks follows very closely that for cholera incidence in the settlement. Primarily, they believe, 'the endemicity of cholera in any locality depends upon the existence in the community of great numbers of (healthy) carriers of non-agglutinating vibrios; secondly, on the occasional conversion in the intestines of a proportion of these carriers by some vital process of the non-agglutinating vibrio into its mutation form, the agglutinating vibrio; thirdly, upon the widespread and continued pollution of drinking water supplies with this mutation form through the unhygienic habits and customs of the people.' In brief, it is the carrier of the *non*-agglutinating vibrio which is the dangerous element. The degree of salinity of the tanks may also have something to do with the persistence of cholera in deltaic Bengal as its natural home.

Interesting as these studies are, they can be paralleled in the case of the dysentery bacilli. There are several points here to be noted. First, that freshly isolated strains which are often non-agglutinable, may become agglutinable after sub-culture: whilst this has frequently been observed with the dystentery bacilli, we believe that Dr. Brahmachari is the first worker to make a similar claim for non-agglutinable vibrios. Secondly, that cholera, although a clinical entity, may not be so with regard to its bacteriology. The recent proposal of Sir Aldo Castellani to divide the group of the dysentery bacilli into true dysentery bacilli, and para- and meta-dysentery organisms, each responsible for bacillary dysentery of different types of virulence, seems to be very apposite in this connection. But the whole position is deserving of much further study. The papers cited, however, show how much importance is being attached at present to the study of the endemic cholera question in India.

A paper by Dr. Lloyd Arnold of Chicago in our issue for August may have some bearing upon this problem. He has been studying the auto-sterilising mechanism of the gastro-intestinal tract from an

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

experimental point of view. In healthy dogs the pH of the intestinal contents changes from marked acidity in the duodenum (pH 2.5 to 6.0) to alkalinity (pH 6.8 to 8.0) in the ileum. Along with this goes a very marked increase in the general bacterial content, and the lower down the small intestine the greater the prevalence of Gram-negative organisms. In a febrile dog the change is less marked. An elevated body temperature causes increased alkalinity of the intestinal contents, and climatic factors in India might make such a temporary elevation of temperature a not abnormal event in persons residing in a hot and humid climate. This might explain the value of dilute acids in prophylaxis against cholera.

From Madras Lieut.-Col. A. J. H. Russell and Mr. E. R. Sundararajan, M.A., discuss the possibility of forecasting cholera epidemics from mathematical data. As the control of the first cases in an epidemic and the isolation of all cases, contacts, and carriers is an impracticable proposition in India, is it possible to forecast epidemics from other data to take measures beforehand? Cholera has a definite downward trend in some areas in India and a general upward trend in others for the period of years examined. The most suitable standard of comparison for the current data of cholera deaths is the median values of the corresponding months or weeks of the preceding decade. It is possible by such studies to classify the different provinces of India into endemic and epidemic areas. By means of the epidemic index, it is possible to forecast epidemics two to three months ahead of their actual occurrence, whilst epidemic index graphs give a very clear picture of the movements of epidemics. Thus a constant watch can be maintained against epidemic cholera, preventive measures be taken beforehand if an epidemic is anticipated, or energy and expenditure conserved if a calm period is expected.

From the United Provinces, Col. Dunn sends us a special note on the position with regard to that area.

Cholera research work was carried on during the year by Dr. Saranjam Khan, who was specially engaged for the purpose, the enquiry being financed by the Indian Research Fund Association, at a cost of Rs. 30,000.

The United Provinces of Agra and Oudh suffer from an average of 61,885 deaths from cholera annually (average of last 50 years). Some of the districts, namely Benares, Gorakhpur, Basti, Azamgarh and Gonda, have never been free from cholera for a single year out of the continuous available records for the last 50 years. The question, therefore, arose:—Are there endemic foci of cholera anywhere in the United Provinces? An answer to this question is of considerable practical importance to the Government of these Provinces in fighting cholera. The mere fact of cholera "being never absent from a division over a considerable series of years"* will not suffice to call that division an endemic area of cholera without excluding all possibilities of importation. Now the five districts mentioned above are all especially liable to importation of cholera, on account either of their proximity to the endemic areas of Bengal and Nepal, or of the location of the most important centres of pilgrimage, or of a combination of both these factors. Investigation on the spot was therefore necessary. In the United Provinces, cholera practically disappears during the months of January and February in each year. We carefully investigated every fresh outbreak of the disease this year (1927). There was a complete absence of cholera from the whole of the United Provinces during the month of January, 1927. Every outbreak during the months of February, March and April was due to importation. During the month of May the foci had multiplied and the disease spread from them throughout the province. The United Provinces were invaded from Bengal and also from Bombay, not as is usually supposed by the successive invasion of contiguous districts from East to West, but through the invasion of far and widely separated pilgrim centres. In this connection we have selected as an observation area the most likely one of the possible endemic centres in the United Provinces, and with the help of a laboratory on the spot we are working on the following lines (August 28, 1927).

(1) The examination of whole stools of the healthy population by the "open-bowl" method for the detection of "carriers."

(2) The examination of the sources of drinking water (which are chiefly wells) for the presence of vibrios, and for the variation in their numbers from month to month with a view to find out the "reservoir" of cholera.

(3) The examination of every case of cholera or choleraic diarrhœa occurring in the observation area with respect to the history, clinical symptoms, and bacteriology, in order to find out if the disease originates in this area independently of importation.

(4) If it does originate independent of importation from outside, has it any connection with the vibrionic flora of the water supply or that of the stools of the general population?

The results will be published as soon as sufficient data have been accumulated.

The causes of the frequent outbreaks of cholera in pilgrim centres is another problem we have tried to investigate. Some of these cholera disseminating centres are of world wide notoriety. The question of Hardwar for instance is not only of considerable importance to the United Provinces but is of equal concern at least to the Government of the Punjab in regard to their policy of fighting cholera. With the help of the laboratory on the spot, certain data have been obtained from Hardwar, and a paper was read at the Seventh Congress of the Far Eastern Association of Tropical Medicine in Calcutta.

The gist of the paper was that:—

(1) Cholera is not endemic in Hardwar, but is imported by the pilgrims.

(2) Some pilgrims passing virulent cholera germs come to Hardwar from the endemic areas of cholera, chiefly Bengal. These persons are not what we may call chronic carriers. They either develop the disease on the way and reach Hardwar suffering from fully developed true cholera, or they are in the incubation period, or are convalescing from a recent attack of cholera, or are what may be called ambulatory cases of cholera.

(3) The cholera germs thus imported by these pilgrims find their way into the Har-Ki-Pairi pool and the Esplanade part of the Ganges, chiefly in the sewage of the town and also through the bathing that takes place in the river.

(4) From the amount of pollution thus received as corroborated by chemical examination this water is totally unfit for drinking purposes.

(5) Some of the pilgrims for various reasons drink this water to the exclusion of any other kind of water or in exceptionally large quantities. It is these people among the pilgrims that are usually attacked by cholera.

(6) As on or about the chief bathing day the amount of pollution reached its maximum, and the number of people drinking from the most polluted part is also at its maximum, a very large number of the pilgrims are infected at that time.

(7) As the gathering is soon dispersed many of these people developed the disease on the way or on reaching home.

Symptomatology and Treatment.—An interesting paper on the blood pressure readings in cholera is one by Dr. A. J. V. McDonnell, Medical Officer to the Anglo-Persian Oil Co. His conclusions are: (*i*) that all cholera treatment outfits should contain a sphygmomanometer; (*ii*) that during an infusion blood pressure readings should be taken after every pint infused, and as frequently as possible thereafter until the patient

* Rogers (Leonard). The conditions influencing the incidence and spread of cholera in India. *Proc. Roy. Soc. Med. (Section Epidemiol. and State Med.)*, 1926, July 19, No. 9. Also a paper read on January 28th, 1927, before the Indian Section of the Royal Society of Arts.

Digitized by Arya Samaj Foundation Chennai and eGangotri

is out of danger; (*iii*) that a pulse pressure of under 20 mm. of mercury indicates the need for a further infusion; (*iv*) that, during an infusion, an increase of less than 4 mm. of mercury in the pulse pressure over the previous reading implies that the infusion should be discontinued; and (*v*) that injections of adrenalin are contra-indicated, as the drug tends to cause a rise in diastolic pressure. A. K. Ghosh writes to enquire whether any of our readers can throw light upon the onset of œdema as a sequel of cholera; his patient developed œdema a week after he had recovered from an attack of cholera; the heart was apparently normal, and the condition yielded at once to oral administration of urotropine.

A very interesting controversy of the year is that between Dr. Tomb and Sir Leonard Rogers in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* with regard to the value of the latter's method of treatment of cholera by infusions of hypertonic saline. Dr. Tomb and Dr. G. W. Thompson plead for infusions of normal—not hypertonic—saline, and claim that hypertonic saline fails to maintain the blood pressure. They further claim that the mortality after treatment only by pills of permanganate is lower than that after either hypertonic salines only, or hypertonic salines plus permanganates. Further, they are of opinion that the administration of opium has a definite place in the treatment of cholera patients when seen before collapse sets in. In reply Sir Leonard Rogers relies upon statistics; he quotes a mortality rate of 59 per cent. with treatment only by rectal and subcutaneous salines, one of 32.6 per cent. with treatment by hypertonic salines only; and one of 20.8 per cent. with treatment by hypertonic salines plus permanganates plus alkalies. The chlorides injected, he claims, combine with the cholera toxins, and these are then excreted by the kidneys. The mortality among cholera cases in the Calcutta hospitals has been reduced to about one-third of its former figure since the introduction of hypertonic salines. To this Dr. Tomb replies by reviewing the earlier literature, and referring to Sellards' successful method of treating cholera by intravenous infusions of normal saline to which 45 gr. of sodium bicarbonate per pint has been added; even intravenous injections of distilled water are of value. To this Sir Leonard replies that he sees no useful purpose in continuing the discussion, that the figures quoted are misleading, and that opinion—as in our opinion, it certainly is—is unanimous in support of the very great value of hypertonic salines.

From China Dr. Alexander Cannon reports on the very great value of Tomb's essential oils' mixture in the treatment and prophylaxis of cholera, and believes that its success lies in the carbolic acid incorporated in the mixture. He concludes 'there is every reason to believe that this treatment saved both Shameen and Canton from a severe epidemic of cholera.' He has also found the treatment useful in cases of food poisoning.

With regard to *prophylaxis*, Col. Russell from Madras writes as follows:—

'The geographical survey of cholera in the presidency was completed during the year and the report now only requires final revision to be ready for publication. Statistics of cholera mortality for the civil population are available only from 1866. The enquiry was based chiefly on these statistics, supplemented by the chronicles and reports of early writers on the subject, and by descriptions of a number of isolated epidemic outbreaks to be found in the Sanitary Commissioner's Administration Reports. The report attempts to give not only a complete and connected history of the different epidemics, but also tries to map out the endemic and epidemic foci, to determine the intensity of infection in different localities, to trace out the course of each fresh epidemic invasion from district to district, to describe its further progress in the districts, and to indicate the influence of such factors as fairs and festivals and meteorological conditions on the spread of these epidemics.

'Field experiments were conducted to determine the relative efficiency of the anticholera vaccine when given subcutaneously and Besredka's Bilivaccin when given by the mouth. This work was carried out in 360 villages with a total population of 647,454. Anticholera vaccine alone was given in 236 villages, and Bilivaccin alone in 52 villages. In the remaining 72 villages the two vaccines were administered side by side, about one-third of the population being given cholera inoculation, another third treated with Bilivaccin, and the remaining one-third being unprotected controls. Every attempt was made to divide the persons living in each house equally into these three groups, care being taken to exclude age and sex factors. The incidence of cholera amongst the immunised and unprotected were carefully noted and the results analysed.

'A high degree of immunity is conferred by both the subcutaneous anticholera vaccine and the oral Bilivaccin. The controls for the former were attacked five to six times more frequently than those who were inoculated twice, and the percentage mortality amongst the attacked was 5.8 times higher in the unprotected group. The controls for Bilivaccin were attacked 5.6 times more frequently than those which received a full course of the vaccine. The percentage mortality amongst those attacked among the unprotected was also nearly twice that among the protected. Statistical analysis of the figures indicated that both vaccines confer a considerable degree of immunity, especially if attacks and deaths occurring within three days after the administration of the vaccine are eliminated, as these persons are already at risk. This seems to be a reasonable elimination. In neither case, however, were the correlation co-efficients obtained as high as those obtained for vaccine lymph as a protective against small-pox. The results of these observations have been published by the League of Nations' Health Organisation in December, 1927.'

DYSENTERY, ENTERIC FEVER, SPRUE, AMŒBIASIS BACTERIOPHAGE.

A study of the figures for the last six years in the annual reports of the Public Health Commissioner with the Government of India (about to be published in a forthcoming book *On the Dysenteries of India* by Acton and Knowles) shows that dysentery is clearly the third most important cause of morbidity and mortality in India, being exceeded only by malaria, and respiratory diseases—including tuberculosis. It is of more importance to India than cholera or plague. Indeed, if terminal fatal infections in such conditions as chronic malarial cachexia, kala-azar, intestinal tuberculosis, etc, with bacillary or amœbic dysentery be included, dysentery may well come to occupy the second place in the mortality rate in India. Yet the disease has never been the subject of any organised Commission of enquiry in this country, and on reviewing the literature with regard to dysentery in India it is remarkable that—from the days of Timothy Lewis, D. D. Cunningham and the early pioneers to those of Sir Leonard Rogers, Lieut.-Col. J. Cunningham and others—the investigations carried out on the disease have always been those by individual and isolated workers. This fact may perhaps be responsible for the very defective teaching with regard to the subject in the medical schools and colleges of India, and for the still almost universal and erroneous belief that amœbic dysentery is of far more importance in this country than bacillary dysentery. This belief is entirely erroneous; for infections with the bacillus of Flexner far outnumber all other causes of dysentery in India.

Perhaps the most important paper of the year is that by A. B. de Castro and V. N. Deuskar in our issue for December on dysentery in the Andaman Islands. A special dysentery ward having been opened of recent years at Port Blair, and special attention having been paid to microscopic and laboratory diagnosis, the results are as might have been expected. Of 582 cases admitted, 351 were cases of bacillary dysentery, and only 231 of amœbic infection. No less than 33 per cent. of chronic latent dysenteric infections were in persons

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

who showed no active symptoms of the disease. May and June are the months of maximal incidence, whilst a secondary peak is visible on the curve in October, due to fresh bacillary infections. The bacillary cases were as a rule definitely ill, the amœbic ones not so. Oedema was a marked symptom in cases of chronic bacillary dysentery. Intravenous administration of emetine in cases of amœbic infection was found to have no advantage over intramuscular injection, and did not prevent the tendency to relapses. Stovarsol is reported on as a useful adjuvant to treatment; yatren as of less value. A marked feature of amœbiasis as seen to-day in India is the surprisingly low incidence of amœbic hepatitis, due in all probability to the almost universal use of emetine for all forms of dysentery. A very interesting résumé of post-mortem findings in fatal cases concludes what is a paper which indicates very clearly that the junior medical school in India—so to speak—is assimilating the lessons of the work of recent years upon tropical dysentery: in fact the authors are to be congratulated on a very clear presentment of the facts, and upon their laboratory studies of the disease.

Major J. B. Hance contributes a valuable article on the use of the sigmoidoscope in the diagnosis of chronic dysentery and in assessing the rate of cure, and describes the conditions and lesions met with in chronic bacillary and amœbic dysentery respectively. As he shows, by the use of the sigmoidoscope an accurate diagnosis as to which type of chronic dysentery is present can often be made even in the absence of confirmative laboratory findings. In the diagnosis of chronic types of dysentery the sigmoidoscope has clearly come to stay.

It is perhaps of less value in cases of acute dysentery, where the laboratory diagnosis is usually quite straightforward; but it is of special value in cases of chronic infection of whichever type, and, further, will yield perfectly fresh and suitable material for laboratory diagnosis. Major Hance describes in detail the sigmoidoscopic appearance in chronic bacillary and amœbic infections respectively, and indicates how simple a matter such instrumentation is; previous preparation of the patient is necessary, but a general anæsthetic is not, and examination can be carried out comfortably after a previous injection of morphia and a cocaine suppository.

Kurchi has long been a favourite drug for the treatment of dysentery in the indigenous systems of medicine in India, and has previously been reported on favourably by Major H. C. Brown, I.M.S. (retd.), and Dr. Henry of the Wellcome Bureau of Scientific Research. During 1927 it has been a subject of special study by Major R. N. Chopra, and Drs. J. C. Gupta, J. C. David, and Dr. Sudhamoy Ghosh, D.Sc., at the Calcutta School of Tropical Medicine. The active principles of the bark of the parent plant *Holarrhena antidysenterica* are the alkaloids conessine and holarrhenine. The former having been isolated in a pure state in the form of its tartrate, its general pharmacological actions on the body tissues were investigated, and also its action on free-living protozoa and on *Entamœba histolytica* in culture *in vitro*. When acting upon the vegetative forms *of E. histolytica in vitro* in an alkaline substrate it is as active as emetine; it has but little action on such parasitic intestinal flagellate protozoa as *Trichomonas hominis*, but has a marked action on such coprozoic intestinal flagellates as *Bodo caudatus*. The conessine salts—contrary to what was thought previously to be the case—are very well tolerated when administered hypodermically; in fact are much better tolerated than emetine. They are unsuitable for intravenous administration owing to their depressant action on the auriculo-ventricular bundle of Hiss, but are very readily taken by the mouth. Major Chopra having presented the present reviewer with a small sample of purified conessine tartrate, its administration in 1 grain doses intramuscularly in the treatment of cases of acute amœbic dysentery was tried in six patients. Clinically it cleared up the symptoms rapidly, but was less rapid in its clinical action than emetine. On the other hand it caused far less pain and induration on injection, and the after-examination of the stools appeared to show that the infection had been eradicated. In previous reports the writer has recorded very good results with the oral administration of Burroughs' Wellcome and Co.'s Tabloid Extract. Kurchi Corticis in acute cases of amœbic dysentery. It would appear that here we may be on the verge of the discovery of a really efficient, and very cheap cure for amœbic infections. At least the present position is well worth following up. Holarrhenine has recently been prepared in a pure state in Col. Chopra's laboratory and is at present under experimental trial. The whole rôle and value of *kurchi* —both in the form of a standardised extract for oral administration, and of the purified alkaloids for hypodermic administration—in cases of chronic amœbic infection is, indeed, well worth trying out; and this special investigation is an excellent example of the only possible way in which discoveries of real value in the ancient systems of medicine in India can be incorporated in the ever-growing volume of modern scientific medicine.

Dr. A. Neave Kingsbury and K. Kanagarayer from the F. M. S. report on the use of antidysenteric serum in cases of infection with the bacillus of Flexner. Sixteen cases are reported on and the doses of serum administered were from 100 to 200 c.c. (the injections being given presumably subcutaneously, though nothing definite with regard to this is stated). With regard to bacteriological results in the stools the results were poor; clinically, however, the serum administration appeared to be of definite value. The general benefit derived from serum administration however is not sufficiently striking to label this line of treatment as a specific cure. (It is to be noted, however, that an anti-Flexner serum can at best be but bactericidal, not anti-toxic, as is the case with an anti-Shiga serum, and that much less result is to be expected from such a bactericidal serum alone.)

Three papers deal with the new method of treatment of bacillary dysentery by the oral administration of the bacteriophage of d'Herelle. The most important is that by Dr. W. Fletcher and K. Kanagarayer from the F. M. S. These workers report that bacillary dysentery is three times as common in the F. M. S. as amœbic, and that Shiga bacillus infections are rare; the chief ætiological agent of dysentery in the States being the bacillus of Flexner. Bacteriophage was administered to 22 men suffering from Flexner bacillus dysentery. The results were not satisfactory and the 'phage' did not seem to assist in the cure of the disease. Three of the patients died during the course of treatment, and dysentery bacilli were recovered from the intestine of each at post-mortem culture. These authors conclude, however, that this trial is not sufficient to condemn the treatment by 'phage'; everything may depend on getting a suitable strain of 'phage' virulent for the specific local strain of dysentery bacillus involved. Major R. H. Malone and Major W. Bird, R.A.M.C., from Kasauli report on three sub-acute cases of Flexner bacillus dysentery treated with bacteriophage orally; in two of these there was an immediate beneficial response, and no dysentery bacilli could be recovered on plating the stools 48 hours after the administration of the 'phage': in the third case the stool was not plated on the 2nd day after the 'phage' administration, but proved negative on the 3rd day. Their results, both clinically and bacteriologically, were very encouraging. (It may be mentioned in passing that the 'phage' treatment has been on trial during 1927 at the Calcutta School of Tropical Medicine, and results to date appear to bear out the above contention; some patients appear to do extremely well in it, others do not; and specificity in the 'phage' strain selected would appear to be an extremely important element in success.)

A still further report by Professor d'Herelle and Major Malone appeared in our issue for November. This applies perhaps rather to the treatment of cholera by bacteriophage than of bacillary dysentery. In three

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

fatal cases no bacteriophage could be isolated from the stools, whereas in two cases which made a rapid recovery a strong bacteriophage was recovered. In 13 out of 23 cases studied, all of whom became convalescent fairly rapidly, the bacteriophage was isolated in increasing virulence in from 24 to 48 hours after the onset of the disease. Professor d'Herelle indeed goes so far as to attribute the natural cessation of an epidemic to the development of active bacteriophage. At the beginning of the epidemic the bacteriophages which are present in the intestine of the patients are of weak order; by degrees "phages" of increasing virulence are elaborated and when these are in the ascendant the epidemic declines spontaneously. Finally, to check an epidemic he suggests the prophylactic inoculation of infected water supplies with a strong strain of "phage," which would be self-propagating, and would even survive in a dried-up well. Such suggestions, the value of which it remains for the future to decide upon, appear to hold out entirely new and tremendous possibilities in the control of epidemic intestinal diseases. The cholera vibrio and the dysentery bacilli are certainly not "natural" inhabitants of water supplies, and if suitable "phages" which are predatory on them can be introduced into such infected supplies and therein multiply at the expense of the pathogenic micro-organisms, we are here clearly on the threshold of an entirely new and most interesting line of prophylaxis.

With regard to *amœbic abscess of the liver* Capt. S. N. Hayes, F.R.C.S., continues the discussion as to whether to aspirate or not in addition to emetine therapy. He concludes that multiple abscesses are probably commoner than single (in which view he is almost certainly right, as many recent papers have shown); that where the swelling is less than two finger-breadths below the costal margin emetine alone, without aspiration, will probably clear the case, but that where the degree of swelling is greater, aspiration is indicated. This is a rational view, and appears to us to correspond to the actual circumstances of the case. Thus we have recently treated several cases of mild enlargement without obvious symptoms of abscess formation with emetine alone, and they have done well. On the other hand a later case presented the picture of a greatly enlarged liver, with typical symptoms and cysts of *E. histolytica* in the stools. He had two full courses of emetine and responded favourably to each, but each time the fever and other symptoms recurred. Finally, he was put on to a third course of emetine and 15 ozs. of pus withdrawn by aspiration; since then he has made a sound recovery. In this instance at least it would appear that aspiration of the (harmless) pus was necessary to relieve pressure and other symptoms. Where secondary infection is present, open operation and drainage is obviously essential. A. K. Bhattacharya records a case of relapsing liver abscess, and those who were familiar with India in the pre-emetine days can remember many similar cases. The patient received an incomplete course of emetine injections in 1925, and relapsed a year later. The liver was enlarged to four finger-breadths below the costal margin, and very tender. Two courses of emetine were now given, but the patient's condition steadily deteriorated. Finally open drainage was instituted, and the patient made a sound recovery. The author speaks of the "failure" of emetine in such cases, but, so far from a failure of emetine, we believe that the emetine therapy contributed materially to the cure: at the same time it would seem necessary to admit that the larger amœbic abscesses of the liver require aspiration or drainage in addition to simple emetine administration.

Enteric Fever.—A paper read by Lieut.-Col. F. A. F. Barnardo before the Medical Section of the Asiatic Society of Bengal, and published in our issue for July, calls for review. The author states that it is not always easy to diagnose the enteric group of fevers, especially during the first week of illness. On the other hand it is very important to establish the true diagnosis during the first week, in order to take proper measures with regard to treatment and prophylaxis. True relapses are uncommon in typhoid fevers, but what are very common are supposed relapses due to secondary infections, such as the invasion of the blood-stream by streptococci through the typhoid ulcers, or the evolution of kala-azar in a patient previously debilitated by an attack of typhoid fever. Of all diagnostic procedures during the first week of illness none is more reliable than blood culture. Finally, the possibility of cases of pyrexia of uncertain origin being anomalous cases of the enteric group of fevers should always be borne in mind. The conjunction of a continuous fever—of however low a grade—persistent headache, constipation, and symptoms of bronchial irritation may be due to persistent influenza, but should always arouse the suspicion of the possibility of enteric fever. An interesting discussion followed the reading of this paper, during which emphasis was laid on epistaxis as an important diagnostic symptom in the early course of typhoid fever.

Sprue.—The special enquiry at the Haffkine Institute, Bombay, into the ætiology and pathogenesis of sprue under the Indian Research Fund Association was continued during the year. In this connection Lieut.-Col. F. P. Mackie reports as follows:

Research work on sprue, started by Col. Mackie and Dr. Hamilton Fairley in 1923 and interrupted from April 1925 to November 1926, has been carried on at the Haffkine Institute, Bombay, throughout the year.

Col. Mackie and Dr. Chitre have made an exhaustive study of the relationship of yeasts (*Monilia*) to sprue. For the isolation and study of cultural characters of yeasts they have used a glucose peptone water acidified with tartaric acid, Sabouraud's medium, Raulin's medium and gelatin stabs. Their study of the structure and life-history of intestinal yeasts leads them to the view that the human intestinal yeasts have been over-differentiated. Relying on the morphological and cultural characters, which they describe in detail, and the power or failure of ferment maltose, they divide the human intestinal yeasts into two main classes, A and K. Class "A" consists of yeasts that ferment maltose; this property is constant and unaffected by prolonged subculture. This class includes yeasts isolated by various observers from the alimentary tract of sprue cases and are regarded by some as pathogenic. They conform in almost all respects to *M. psilosis* (Ashford). Class "K" are maltose non-fermenters. This class includes the "wild yeasts" and are similar if not identical with *M. kruzei* (Castellani).

In their study they isolated *M. psilosis* in 29 out of 71 cases of sprue (40 per cent.), in 10 out of 27 cases of intestinal disease not sprue (37 per cent.), in 14 out of 36 cases of other diseases (38 per cent.) and from about 50 per cent. of the intestinal tracts of healthy men and animals examined. *M. kruzei* was present in about 50 per cent. of sprue and other human diseases and in a similar proportion of healthy men and animals. They came to the conclusion that "the distribution of these classes of yeasts was similar in sprue to that in other diseases, and there was no undue frequency of any type of yeast in any diseased or healthy condition, and therefore there is no evidence to show that any of these moniliæ bear a causative relation to sprue.

These workers have amplified their clinical observations by animal experiments. They employed guinea-pigs, rabbits and monkeys as experimental animals, and gave *M. psilosis* cultures by intraperitoneal injection, intravenous inoculation and *per os*. They also infected some monkeys by feeding them on the fæces of sprue patients. The monkeys so infected had been previously devitalised by being fed for several weeks on a diet deficient in vitamin C. In none of the animals however inoculated and whether in a condition of vitamin C deficiency or otherwise, was there any development of an intestinal condition resembling sprue, nor was any condition of anæmia produced in the animals which were especially examined for the condition; though *M. psilosis* is undoubtedly toxic for some animals especially by the intravenous route.

Col. Mackie and Dr. Gore have investigated the bacteriology of the alimentary tract in sprue. So far they have found no bacillus peculiar to sprue. The commonest organism of pathogenic significance met in the condition is a "Morgan-like" bacillus. A vibrio-like organism has been recovered from the duodenal contents and the blood of three cases but its significance is not yet clear. Hæmolytic bacteria were commonly found in sprue stools, a fact which may throw some light on the anæmia.

Col. Mackie and Dr. Billimoria have examined the blood of 28 cases of sprue during the year. The results correspond closely with the results of a series of 25 cases reported before by Fairley and Mackie. They come to the conclusion that "profound anæmia where the red cells are below a million is rare in sprue, but is met with in terminal stages—sometimes as a result of a blood crisis where the count may fall by two million per c.mm. within a week. Severe anæmia counts between 1 and 2 millions are frequent in the later stages of the disease. Moderate anæmia is present in practically all cases of early and fully developed sprue." They find the blood picture to be constant and readily distinguishable from that of pernicious anæmia. Its characteristics are a marked anisocytosis, the megalocytes preponderate, the poikilocytes are few, and polychromatophilia is present but generally scarce, and a total absence of nucleated red cells. The average colour index was 1.1, with fully half the cases below 1. They sum up the blood condition as follows:—"A megalocytic anæmia without signs of regeneration, i.e., an aplastic anæmia."

The senior author has made post-mortem examinations of ten cases of sprue. He saw little naked eye change in the organs, except perhaps thinning of the gut wall and reduction in the size of the liver. But he is inclined to regard this a part of a general process of emaciation. He found no evidence of inflammation or ulceration in any part of the intestinal tube. He however found the condition of the bone-marrow to be characteristic. The marrow of long bones, like the tibia, in all cases was in a condition of more or less complete aplasia. This condition is in keeping with the state of the blood picture. All the material obtained at these examinations has not been fully worked up yet.

Major Sokhey, Mr. Gokhale and others have studied the liver function in sprue. They employed the levulose tolerance test, the Van den Bergh reaction, the brom-sulphalein test of Rosenthal and White and determined the nitrogen partition of blood in 13 cases of sprue and came to the conclusion that liver function was not impaired.

Major Sokhey and Mr. Malandkar have also studied the pancreatic function in sprue. Employing Saxon's wet method of fat analysis of fæces, they found that all but one of their series of seventeen cases showed normal splitting of fat. Quantitative estimation of diastase, trypsin and lipase of duodenal contents, showed these ferments to be present in normal amounts. The conclusion they arrive at is that the pancreas, as far as its external secretion is concerned, functions normally in sprue.

A still further publication with regard to sprue is one by Dr. Hamilton Fairley in the *Medical Journal of Australia* with regard to the differential diagnosis of pernicious anæmia and sprue. This is reviewed by Dr. Manson-Bahr in the *Tropical Diseases' Bulletin* as follows:—

"Referring to the differential diagnosis between pernicious anæmia and sprue, Fairley finds a colour index above 1 in 56 per cent. of sprue patients. Difficulty in differentiation was only experienced when the alimentary features were atypical. In this group the most reliable clinical features were emaciation or a history of marked loss of weight, the passage of bulky stools, abdominal distension and the complete absence of any neurological signs suggestive of subacute combined degeneration of the cord. Even in latent sprue there is definite limitation on the part of the intestinal mucosa to absorb fat; this becomes obvious directly the fat content of the diet is increased. In 36 consecutive cases throughout all periods of the disease, during and after treatment, it was shown that the fat averaged 49.1 per cent. of the dried fæces. Of this 7 per cent. represented neutral fat, 17.3 per cent. fatty acid, and 22.8 per cent. was in the form of combined fats. Defective fat absorption is not a feature of pernicious anæmia. The blood in sprue may show the characteristics of an aplastic pernicious anæmia and the bone-marrow the corresponding changes. In the long bones gelatinous, greenish marrow deficient in erythroblastic elements is observed. On the other hand, evidence of intravascular hæmolysis is limited in sprue; the deposition of hæmosiderin in the liver and kidney is also not marked, whilst out of 16, nine cases gave Van den Bergh readings of under 0.5 units and seven exceeded this figure.

The fractional test meal affords most important data from the standpoint of differential diagnosis. In pernicious anæmia the achlorhydria is a true *achylia gastrica*, due to a secretory defect. Analysis of total and free acid curves in a consecutive series of 26 cases of sprue demonstrated that four were hyperchlorhydric, seven normal, and eight hypochlorhydric. In the achlorhydria of sprue, hydrochloric acid is being secreted efficiently, and its absence from the gastric content is dependent on neutralization by alkaline fluids derived from the duodenum. Experience in Bombay was convincing that sprue and pernicious anæmia are distinct clinical entities."

KALA-AZAR.

Epidemiology.—Major H. E. Shortt reported a case of kala-azar in a man who had only paid two short visits to endemic areas in the plains; one visit was 9 months and the other 3 weeks before the onset of symptoms. It is presumed that he acquired the infection during the first visit.

Major P. Savage reported a case of kala-azar in a boy at Sanawar in the Simla Hills; the boy did not appear ever to have been in a known endemic area. A second patient who was also apparently a case of kala-azar had not been away from Sanawar for many years. In this connection Major Sinton pointed out that *Phlebotomus argentipes* had been discovered in Sanawar.

T. K. Raman gave details of 406 cases of kala-azar admitted to the Madras General Hospital during 1924 and 1925. He reported that sandflies in Madras were plentiful during July, August and September and again in April, but rare during the cold weather months and hot dry months.

Transmission.—No definite advance has been made during the year in the kala-azar transmission problem although a number of papers which fill in the gaps in our knowledge on various subjects and which may have some bearing on this problem have been contributed.

Members of the Kala-azar Commission in Assam, Major H. E. Shortt, J. P. Barraud and Captain A. C. Craighead, have reported the successful infection of a white mouse inoculated intraperitoneally with the intestinal contents of *Phlebotomus argentipes* infected with *Leishmania donovani* The same authors describe comprehensive transmission experiments with *Phlebotomus argentipes* and *Leishmania donovani* which they summarise in the words, "Sixty experimental animals subjected to 184 bites from a minimum of 152 sandflies, *Phlebotomus argentipes* known to be infected with *Leishmania donovani* have in no instance developed kala-azar. H. E. Shortt, A. C. Craighead, Khazan Chand and C. S. Swaminath have given an account of the non-flagellate forms of *Leishmania donovani* found in old cultures in their relationship to the production of infection in animals and have come to the conclusion that the presence of these bodies in cultures is not necessary to the production of infections. The first and last writers mentioned above have also given in another publication a full description of the mode of formation and morphology of these bodies.

L. E. Napier in a short series of observations on the infectivity of the flagellate form of *Leishmania donovani* showed that five-day-old cultures would give rise to infection in mice, he further tentatively concluded that early cultures in which the flagellates are scanty give

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rise to infection less readily than do older, richer cultures, but that after 12 days or so, there is little increase in the infectivity of the culture, and that the individual flagellates become less infective at some age between 12 and 28 days.

L. E. Napier and R. O. A. Smith reported the development of *Leishmania donovani* in the sandfly *Phlebotomus papatasii;* 2 per cent. of specimens fed on kala-azar patients were infected, whereas 42 per cent. of specimens of *Phlebotomus argentipes* fed under similar circumstances became infected.

Clinical.—B. N. Bhadari reported a case of opacities in the lens occurring as sequel to kala-azar. R. P. Chatterjee reported a case of arrhythmia of the heart after injections of urea-stibamine; the pulse dropped to 36. The arrhythmia disappeared on the administration of atropin, but reappeared when another urea-stibamine injection was given.

Diagnosis.—Lieut.-Col. E. C. Hodgson, A. C. Vardon and Zorawar Singh have described a blood sedimentation test for the differentiation of malaria from kala-azar and other fevers. H. E. Shortt, S. Das, and Chiranji Lal have given an account of the finding of parasites of kala-azar in the peripheral blood. By the technique described even a short search for the parasite yielded a high percentage of successes, 78.7 per cent. The factors associated with the presence of the parasites in the peripheral blood are discussed.

Major R. N. Chopra, J. C. Gupta and J. C. David made the observation that the addition of 4 per cent. solution of Stiburea (Urea-stibamine) and certain other pentavalent compounds of antimony when added to the serum of a kala-azar patient caused coagulation of the serum and that when this solution is added to a normal blood no coagulation occurs. They suggested that this phenomenon might be adopted as a diagnostic test in kala-azar. The two senior writers together with N. K. Basu extended these observations; they found that the percentage of positive tests was higher than with the aldehyde test; five cases of early kala-azar, in which the diagnosis was subsequently confirmed by blood culture, gave positive reactions with antimony but negative with formalin. In certain diseases, other than kala-azar, in which there is enlargement of the spleen a positive antimony test occurs but in these cases the reaction is not strongly positive. They suggested an even simpler test by which two drops of blood from a finger are received into 2 per cent. potassium oxalate and 4 per cent. solution of antimony added. They say that by this test they obtained results parallel to the antimony-serum test.

In a later communication these three writers point out that there has been a certain amount of misunderstanding about the reading of the antimony test. For the test to be considered positive a thick flocculent plug should form at the junction of the antimony solution and serum; this plug is not easily broken up and does not dissolve when the test tube is left standing for 24 hours. They also point out that certain samples of urea-stibamine appear to give positive results with normal serum so that whenever possible a control of normal serum should be put up at the same time. Further they have observed that by diluting the serum 8 or 10 times it is possible to exclude certain cases of enlarged spleen, non-leishmanial, in which there was a positive reaction with the strong serum; when diluted in this way these sera give a negative reaction. The test was performed in 30 cases of dermal leishmaniasis; it was negative in all but one case.

Following on Chopra's original observation of the precipitation of kala-azar serum by the addition of antimony solutions, L. E. Napier independently worked out a technique for the application of this phenomenon as a test for kala-azar. In view of the fact that 4 per cent. solution of the antimony compounds appeared to give positive results in many cases of enlarged spleen which were not cases of kala-azar, he suggested using a more dilute solution of Stiburea. In a paper on the subject he drew the following conclusions:—

"The above-described reaction occurs with a number of pentavalent antimony compounds and the intensity of the reaction appears to vary according to the therapeutic efficiency of the compound used.

The diagnostic value of this test appears to be equal to that of the aldehyde test, but further experience is necessary.

It has two distinct advantages over the aldehyde test, namely, that only a small quantity of serum is required, and that a clear-cut result can be obtained when the serum is milky, as is often the case with children's serum.

The test is best performed by adding 2 drops of a 24-hour-old serum to 2 c.c. of a 0.25 per cent. solution of Stiburea, or 2 drops of freshly separated serum to 2 c.c. of a 1 per cent. solution of Stiburea, agitating, and leaving on the laboratory bench for 10 minutes. If the serum is from a patient suffering from kala-azar a heavy flocculent precipitate will form which will separate within 10 minutes, leaving a clear supernatant fluid."

A. N. Sen reported the results of the antimony test in 42 patients under his charge of which 20 cases of kala-azar; he considers the test of considerable value.

Pathology.—C. C. Basu described a method of staining Leishmania in the tissues by using Gorriz's modification of Bielschowsky-Cajal's silver staining method. The stain does not fade. C. Ray made some further investigations into the albumens and globulins of kala-azar and syphilitic bloods.

Prophylaxis.—L. E. Napier and P. Foster in a paper on the control of kala-azar on tea estates concluded that by segregation and treatment alone the spread of kala-azar on a tea estate cannot be stopped, but by this means it can be controlled; that a lesser degree of success can be expected from treatment alone; and that transfer of the lines can be expected completely to cut short an epidemic. Whether it is advisable to advocate the transfer of lines in view of other considerations is an entirely different matter. It is seldom possible to carry out a complete transfer in less than a year; by this delay the value of the measure is considerably reduced. Furthermore it is very unpopular with the coolies and is expensive. On the other hand the treatment of the disease is very satisfactory these days and a cure rate of at least 95 per cent. can be anticipated. Special circumstances must dictate the line of action to be taken.

Treatment.—L. E. Napier contributed a paper on the treatment of 61 patients by No. 693, a pentavalent compound of antimony. In this series there were no deaths and, except that two patients proved entirely resistant to this as well as all other forms of antimony treatment, no relapses. The writer was able to get into touch with 50 of the patients all of whom had remained in good health for periods of at least six months after discharge. A number of the patients were cured after 8 injections and it was calculated that a course of 10 injections should produce a cure rate of *at least* 93.3 per cent. The same writer pointed out in a letter to the *Indian Medical Gazette* the value of Aminostiburea, more especially in the treatment of resistant cases. L. E. Napier and K. C. Haldar in a paper on the cure rate in kala-azar point out that very large number of patients who receive a course of treatment which is usually considered totally inadequate are actually cured; the cure rate was about 40 per cent. amongst those receiving less than 1 gramme of sodium antimony tartrate, but 87 per cent. amongst those receiving more than 2 grammes of this salt. C. C. Sanyal reports good results from the rectal administration of Stiburea in kala-azar.

Dermal leishmaniasis.—Lieut.-Col. H. W. Acton and L. Everard Napier gave a detailed account of post-kala-azar dermal leishmaniasis. Their observations were based on 44 cases of this condition. They describe the three stages of the disease and the pathological findings associated with these stages. The paper is profusely illustrated.

B. M. Das Gupta discussing this condition from a laboratory point of view says that it is seldom possible to find the organisms in a smear from the depigmented lesions, but that on several occasions he has grown flagellates from a piece from a depigmented patch. On one occasion he obtained a flagellate culture from the peripheral blood of a patient who had typical dermal lesions; the patient had no enlargement of the spleen but for some time she had had fever which was not amenable to quinine. In another communication he reports an experiment which, he considers, proves that organism found in the dermal lesions is *Leishmania donovani* and not *Leishmania tropica*. He inoculated the contents of a 12-day-old culture, obtained from a dermal leishmaniasis nodule, into the peritoneal cavity of a mouse; a visceral infection followed.

U. N. Brahmachari and A. M. Dutt reported a case of dermal leishmaniasis in which parasites were present in the peripheral blood and the patient had symptoms of kala-azar.

Oriental Sore.—Dr. Ganapati Panja reports infecting a patient by means of a 1-week-old culture of *Leishmania tropica*. He inoculated 1 c.cm. of the culture; three weeks later a nodule appeared which eventually, one year after the inoculation, broke down and formed an ulcer. Leishmania were found in the ulcer. (The writer's claim that this is the first occasion on which this experiment has been successfully performed is not valid.)

F. de Mello and V. Camotini report a case of oriental sore in which the infection was apparently contracted at Goa.

Owen reports a case of oriental sore in Bagdad in which there were 250 lesions.

Treatment.—R. L. Varma advocates berberine sulphate in the treatment of oriental sore; he claims to have had good results after local injection.

Captain P. V. Karamchandani gives a very brief analysis of the treatment of 337 cases of oriental sore. Of these 300 were treated by sodium antimony tartrate injections. Of the other methods employed he considers berberine sulphate the most promising.

Canine leishmaniasis.—C. R. Chadwick and C. McHattie give a very detailed account of the cutaneous lesions occurring in dogs in Iraq. In Bagdad the disease is confined almost entirely to the cold weather months.

Publications.—During the year L. Everard Napier published a book on Kala-azar. The book was designed to replace the book written by himself and Dr. Muir about four years ago. It has been almost entirely re-written and all the latest advances in our knowledge of the disease, especially of its ætiology and treatment, are embodied in this new publication.

TROPICAL FEVERS, TYPHUS, DENGUE, WEIL'S DISEASE.

The subject of *tropical typhus* continues to attract attention. Lieut.-Col. L. H. L. Mackenzie draws attention to cases suggestive of this disease in the Gilgit Agency; louse transmission could be excluded, and it was never epidemic. Two further cases at Kumaon are described in our issue for May; one in a European schoolgirl from Naini Tal; the other in a European male, aged 64, who died in a state of coma on the 13th day of illness. There was no history of tick bite in either case, but the patients were free from lice. Dr. R. N. Bannerji describes a further case, a Mahommedan pleader in Allahabad; the rash came out on the 6th day, there was coma and glycosuria, and the fever finally fell by rapid lysis. No ticks or lice were found on the patient.

From the United Provinces we have received the following special report on this disease by Capt. D. Clyde, Assistant Director of Public Health (Malariology), U. P.

From an investigation into tick typhus at Bhim Tal in July and August 1927, it would appear that reliance cannot be placed on the past statistics dealing with the incidence, etc., of the disease as recorded in the local hospital since.

(*a*) True typhus and tick typhus were not recorded separately.

(*b*) Several cases diagnosed as probable typhus were certainly neither typhus nor tick typhus.

(*c*) A clinical diagnosis only is made in almost all hospital cases, blood examinations are very seldom made. The routine treatment given is small doses of quinine (7 grains twice daily) to all classes of fever.

(*d*) Subsequent histories are seldom followed up and cases seldom visited in outlying villages. The evidence on which a case mortality of 5 per cent. is locally based would appear erroneous, as true typhus, enteric fever and malaria are not eliminated by a differential diagnosis.

(*e*) Reports from friends coming in from outlying villages are relied upon; these are extremely erroneous. It is noteworthy that in some cases a "rash" on which a probable diagnosis of tick typhus had been based, turned out to be sudamina.

Of 43 cases of illness among villagers examined 38 were malaria (9 M. T.; 1 B. T.; 2 mixed M. T. and B. T.; 26 old clinical malaria), 1 was pleurisy and 4 gave a history corresponding to the tick typhus group of diseases.

These cases were four motherless children of a cultivator in village Sanguri which is about 1,000 feet above the lake in Bhim Tal. The ages were 4, 6, 6 and 10 years respectively. The youngest child contracted the disease on the 1st of June, the second child on the 9th of June, the third child on the 16th of June and the eldest child on the 18th of July, 1927. These cases were seen on 17th July, 1927. No history of tick bites was forthcoming. The ticks found in the vicinity were *Hæmaphysalis* only (on dogs and goats). The local anophelines were *A. listoni, fuliginosus*, a few *maculipalpis* and a few *willmori* at the date of investigation.

There would appear to have been little possibility of the vector or reservoir of infection being associated with the lake region in these cases.

The onset in all four cases commenced with malaise and frontal headache; 24 hours later fever commenced. The fever in all cases appeared to be high and of sudden onset. There was no rigor in any case. The fever remained high for 10 to 12 days during which the patients were prostrated. On the 10th or 12th day the temperature dropped and a rash appeared. Slight temperature continued till the 18th or 19th day. The rash and fever disappeared together on the 18th or 19th day.

The rash appeared first on the 10th or 12th day of fever on the supra-clavicular region and had spread within 24 hours to the front of the chest and the upper part of the abdomen. The face, legs, back and lower abdomen were free from the rash in all cases. The rash was apparently macular, discrete and whitish, the individual spots were about the size of a pin's head. It faded in the order of occurrence from the supra-clavicular region downwards. In all cases the rash lasted from 6 to 9 days and was followed by desquamation. The last case to become infected showed branny scales on the front and back of the chest and discolouration of the skin over the same area on 17th July, 1927. Convalescence was extremely rapid in all cases.

It was only possible to examine the blood of the eldest child.

(1) Differential count:—

Eosinophiles	1%
Polymorphonuclears	61%
Small mononuclears	32%
Large mononuclears	6%

Arneth's count within normal variation.

(2) No malarial parasites. No abnormality in size, staining, etc., of red cells.

(3) Agglutination against:—

(*a*) *B. typhosus*—positive in 1 : 8, negative in higher dilutions.

(*b*) Para A and B—negative in all dilutions.

(*c*) *M. melitensis*—negative in all dilutions.

(*d*) *Proteus* X19—negative in all dilutions.

(Fletcher's strain of X19 was not available.)

No new cases of continued fever with rash were found between 16th June and 1st October, 1926.

Dengue.—Major G. H. Dive, R.A.M.C., gives an account of dengue in Aden, where he states that this disease is endemic. Troops arriving in the winter months are most commonly attacked between April and July, whilst there is a second infective season about September. A considerable degree of immunity is afforded by one attack. Both infective periods correspond with the optimum season for mosquito development, and it is very doubtful whether true sandfly fever ever occurs in Aden. Various other diseases, such as influenza and rubella, have previously been confused with dengue in the returns from Aden.

Weil's Disease.—As noted in Knowles' *Introduction to Medical Protozoology* (published during the year) slides kindly sent by the observers in the Andamans and fixed material from the cases of epidemic jaundice in the Andamans show undoubted leptospira, and the epidemic jaundice of the Andamans must now be considered to be Weil's disease. Dr. D. L. Galloway describes five cases in Malaya, and the *Malayan Medical Journal* a further series of four cases. Leptospira were found in experimentally infected guinea-pigs; one of the convalescent patients—a Japanese—travelled to Japan, where six weeks later his daughter contracted the infection, and the original patient's urine still showed leptospira. It is clear that Weil's disease extends in sporadic form throughout the Andamans and the Malay archipelago, and it will probably be found to occur in Burma and Bengal.

A. Paes discusses a curious epidemic disease which has within recent years affected the child population of Nova Goa. In the benign type the condition begins with fever and vomiting; in severe cases there is uncontrollable vomiting, acute constipation, and great tympanites; in fulminant cases there is complete unconsciousness and the child dies within a few hours. The meningococcus was found in some cases, but the symptoms are quite unlike those of cerebro-spinal fever; so far from there being rigidity, there is complete muscular relaxation; and the administration of anti-meningococcus serum did not improve results. The case mortality is about 30 per cent., and the best line of treatment is a brisk purgative at the onset of the disease. The symptoms are those of an overwhelming toxæmia, but it is remarkable how rapid and complete is the recovery in the non-fatal cases.

K. C. Ghose records the results of treatment of *lobar pneumonia* by daily intravenous injections of iodine; every alternate case was treated and the others left as controls. On a series of 20 cases treated and 20 controls he considers that the iodine treatment does not affect the progress of the disease, but there appears to be much less toxæmia in the cases so treated. The injections should be given very slowly.

Major H. Hingston writes on *ketosis* in acute fevers, dealing chiefly with fevers of the enteric group. The examination of the urine for acetone and diacetic acid is of extreme importance and forms an important basis for treatment. None of the pathological investigations are infallible, though early blood culture is probably the best. If acetone or diacetic acid is found the patient is put on to an alkaline mixture, potassium citrate, dr. ii, liquor ammoniæ acetatis dr. ii, sodii bicarbonatis gr. xxx, spir. ammon. aromat. m xxx, and water to the oz.; one dose every four hours or so until the urine is acetone-free. Two drachms of glucose are also given every two or four hours. The value of the method is shown in a table of 20 cases, of whom only two proved fatal—one from subsequent otitis media. The same line of treatment is also valuable in pneumonia.

LEPROSY.

"Widespread activities in dealing with leprosy in India have centred round the Indian Council and the Provincial Branches of the British Empire Leprosy Relief Association," writes Dr. E. Muir. "The work of this organisation, founded in 1925, is developing satisfactorily. Research work has been given a prominent place, and training of doctors in leprosy work at various centres and at the Calcutta School of Tropical Medicine has been taken full advantage of. A survey under the experienced leadership of Dr. Isaac Santra has been begun with the object of locating the most highly endemic areas and the most affected classes of people, and studying the causes which make for this excessive endemicity. Sample surveys have already been conducted in Bihar and Bengal with interesting and important results. Large numbers of special leprosy clinics have been begun both in towns and rural areas, and the popularity of these clinics is best evidenced by the fact that in two of them between 400 and 500 patients attend every week. What is perhaps even more important is the interest which private practitioners are taking in the treatment of the disease, and the hopelessness and fear of contagion which formerly prevented doctors from attending leprous patients is giving way to a more reasonable attitude. Literature, posters, and lantern slides have been prepared and are available from the Secretary to the Association. Leprosy is perhaps the only disease against which there is a central organisation with influential branches in every Province, and if the disease was more or less at a standstill, neither increasing nor diminishing when practically no effective steps were being taken to stamp it out—as was the case a few years ago—, surely it is not too sanguine to expect a considerable diminution of its frequency now that so much effort is being put forth and so much intelligent interest taken. Other countries are taking an interest in what India is doing, and doctors from the Philippines, Egypt, Greece, the Gold Coast, and Nigeria have been sent to India to study the methods adopted here."

Epidemiology.—Dr. E. Muir deals with the factors influencing the endemicity of leprosy. The chief direct causes of high endemicity are dietetic, the poor diet available being supplemented in some areas by decomposing fish, meat, rice, etc. Caste and race have a certain bearing due to habits regarding diet, and to certain aboriginal tribes being driven into the less fertile tracts or into serfdom or debt. Venereal diseases, which predispose to leprosy are especially common among certain low castes. The poor soil of certain tracts, its porosity and the slope of the land are of importance, as the crops are correspondingly poor or precarious and dietetic errors result. While a very low humidity makes for a low incidence of leprosy, as shown by Sir Leonard Rogers, there seems to be no close correlation between humidity and leprosy. Excessive rainfall, by washing away and impoverishing the soil, by leading to mosquito breeding and malaria, and in other ways, may have an indirect effect.

In our issue for August Dr. Muir deals in more detail with leprosy in the Bengal-Bihar border line. Here, in the Sonthal Parganas the incidence of leprosy is notoriously high; in a school of 300 boys 11 were found infected, whilst even the unskilled census returns give an incidence of 20 per mille, and this figure is probably well under the mark. On the Chota Nagpur plateau the aboriginal lives in his natural freedom and security from infectious diseases, out of touch with civilization. On the fringe of this area he penetrates into a less healthy area where he has his first contact with civilization, and the reaction of contact makes or means all the factors that make for leprosy: clothes, crowding, poor food, venereal disease, etc. In this area the raw material in the form of aborigines coming from non-infected tracts becomes both leprolised and syphilised. Finally, beyond this is a broad fringe into which the constantly migrating infection gradually tails off, with areas of increased incidence in the larger cities from imported infection. If everyone in Calcutta suffering from leprosy were to be cured to-morrow there would be a still further influx of the infection the next day. Hence the necessity for incessant propaganda work, for leprosy clinics, for the training of *mofussil* medical men with regard to the diagnosis and treatment of early cases. Dr. Isaac Santra continues this article, giving a more detailed account of leprosy as it exists in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Manbhum District, and of the steps being taken to combat it. The incidence in the general population is here 6.49 per mille, and the low Bauri caste—usually the servants of Brahmins—are especially affected. The Sonthals, aborigines of a much higher general standard of cleanliness and living, are much less affected. There can be no hope for the Bauris until society elevates them to human conditions. The lines along which this problem is to be tackled are incessant propaganda, an attempt to introduce fresh milk and vegetables into the dietary of the people, the opening of special leprosy clinics, confidential registration of lepers, periodical examination of school children, and training of medical men.

Symptomatology and Diagnosis.—Major R. B. Lloyd, Dr. Muir, and Rai G. C. Mitra Bahadur deal with the influence of syphilis on leprosy as indicated by the Wassermann reaction. This is a final report summarising the results of several years of work. The percentage of positive reactions—in mild cases of leprosy 15 per cent.—is not higher than that in the general control population. These positive reactions are due to co-existing syphilis, and not to the leprosy. Further, this is true even in the more advanced cases of cutaneous leprosy, where the figure may rise to 50 per cent. of positive reactions. The obvious deduction is that syphilis is a factor which increases the severity of leprosy in the patient and leads to more severe leprotic symptoms and signs. Hence, in such cases treatment of the syphilitic infection may do very much towards improvement of the leprotic condition. In such cases Avenyl, "Hg. 33" (B. W. & Co.) has proved a most useful drug in treatment. It becomes necessary to provide anti-leprosy clinics with facilities for the carrying out of the easier serological tests for syphilis, of which the Kahn flocculation reaction is preferred. Anti-leprotic treatment has no effect upon the positive Wassermann reaction, but anti-syphilitic treatment not only results in a negative Wassermann reaction, but in very marked improvement in the leprotic condition.

The effect of coincident kala-azar in leprosy has also been studied by Dr. Muir during the year. Kala-azar has been endemic in recent years at the Albert Victor Leper Asylum, Gobra, Calcutta, and affected 16 of the lepers there. Of these 16 cases 3 died, and the other 13—after recovery from their kala-azar—showed a very remarkable improvement in their leprotic condition. Almost any prolonged febrile condition may favourably influence the course of leprosy. On the other hand, in 5 cases where early leprosy appeared during the latter part of a course of treatment of kala-azar the leprosy was apt to be progressive. Prolonged febrile diseases appear to favour the breaking down of lepra bacilli, this is followed by a general bodily reaction, the further breaking down of other lepra bacilli, and their more rapid elimination.

Dr. J. M. Henderson of the British Empire Leprosy Relief Association discusses the gland puncture findings in leprosy. The value of this method of diagnosis has been the subject of considerable discussion in the past. A total of 93 patients were "punctured"; 57 of whom had been under treatment for a variable period, 36 of them new untreated cases. The later the disease, the more constant was the finding of lepra bacilli in the smears of gland puncture juice. In a small proportion of early cases gland puncture may sometimes demonstrate the bacilli where the examination of films from skin lesions has had negative results, but taken in general the method does not appear to be of value in assistance in the diagnosis.

Treatment.—The largest number of papers published during the year deal with treatment. Pride of place must be given to the full discussion at the Section of Tropical Diseases and Parasitology of the Royal Society of Medicine at which a paper by Dr. Muir was read, and Sir Leonard Rogers, Dr. R. Cochrane, and other workers from India took part. The following abstract of this discussion is taken from our contemporary, the *Tropical Diseases' Bulletin*, and well summarises the present position with regard to the present-day treatment of leprosy.

This important joint discussion at the Royal Society of Medicine by the Sections of Tropical Diseases and Parasitology, Dermatology, and Therapeutics and Pharmacology was arranged at the request of the Dermatological Section, which opened it. J. M. H. MacLeod reviewed the subject for the dermatologists, and dated the modern treatment of leprosy from the first leprosy international congress at Berlin in 1897, when the old hereditary theory was abandoned in favour of the contagious one. In 1909 it was declared that while leprosy is not incurable we do not possess a certain cure. He next pointed out that:—"Since then great advances have taken place, chiefly through the researches of my colleague at the Tropical School, Sir Leonard Rogers, and his associate, Dr. Ernest Muir in Calcutta; Power, Dean and Macdonald in Hawaii: Denny and Brill, in the Philippines, and others." After pointing out the difficulties in estimating the value of treatment in leprosy, with illustrative cases, he discussed the general, local and specific treatment; and included under the last class metallic preparations, sera and vaccines and vegetable oils and their derivatives, especially chaulmoogra oil; and he mentioned the advance made when soluble salts and esters of the fatty acids suitable for injection were introduced, that of *Hydnocarpus wightiana* being now most used. During the past two years he had been using at the St. Giles' Homes for British Lepers certain of these preparations, such as chaulmoogra oil, hydnocarpus oil, E.C.C.O., sodium morrhuate, sodium gynocardate, etc., by subcutaneous and intramuscular injection, but not intravenously owing to the vein trouble that may ensue; as the result of this experience he thinks it advisable to keep an open mind with regard to the specific action of these remedies, for while some patients held their own and improved in their general health, others were unaffected or showed only temporary benefit, and in none could a cure in the scientific sense be claimed. It was doubtful how far the arrest in some cases was due to the natural course of the disease, and treatment on general hygienic principles may help to increase the resisting powers of the patients.

J. H. Sequeira related a case apparently greatly benefited by "protein shock," which he thinks may be the real cause of the beneficial results in a number of the so-called cures. G. Pernet spoke of his experience in the treatment of leprosy in collaboration with Radcliffe-Crocker and later especially with perchloride of mercury injections, which were disappointing. He thought chaulmoogra oil the best remedy, but did not mention having used the new soluble derivatives. G. C. Low spoke of his experience with Manson's cases and subsequently with disappointing results, including two cases treated by recent methods, but he thought protein shock might sometimes have a good effect.

The Dermatological Section speakers were followed by T. A. Henry for the Pharmacological Section, who discussed the chemical composition of the different vegetable oils used in the treatment of leprosy, first studied by Power. He pointed out that gorli seed oil from West Africa was the only oil containing pure chaulmoogric acid, without the usual admixture of hydnocarpic acid of the other varieties; but pure ethyl chaulmoograte made from gorli seed failed in trials in leprosy. These results, he said, are supported by early observations of L. Rogers showing that the salts of the higher melting point fractions, mainly chaulmoogric acid, were less effective in leprosy than the lower ones containing more hydnocarpic acid, for the latter will be liquid or nearly so at the body temperature. He next spoke of a Hg33, or myristoxy-mercuri-*m*-hydroxybenzaldehyde, made in his laboratory, and soluble hydnocarpus oil. E. Muir had used the mixture in Calcutta by injection in syphilitic lepers with very satisfactory results.

The Tropical Disease Section's contributions to the debate were opened with a paper written by E. Muir, in which he first emphasised that we have no specific cure for leprosy in the sense of quinine in malaria and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

antimony in kala-azar; yet "there is a line of treatment which will cause the permanent disappearance of all active signs of the disease in early cases, so that the patient is for all practical purposes *cured*, though, if a marked reduction in his general health occurs later there is always the possibility of a relapse." Leprosy is a more remediable disease than tuberculosis, and leprosy can almost always be diagnosed clinically long before the bacilli can be found in the lesions, when the prognosis is far more favourable than in the corresponding stage of tubercle. Muir's well known lines of treatment by dealing with complicating diseases, diet, exercises, the injection of hydnocarpus oil, and its derivatives, external applications and surgical measures, were next described; the necessity of a close acquaintance with the stages and phases of the disease to allow of successful treatment and correct estimations of the value of drugs was emphasised. The fallacies due to limited experience and to the subsidence of acute phases independent of treatment being attributed to drugs were pointed out. His present routine treatment is the intramuscular or subcutaneous injection of 4 c.c. gradually increased to 10 c.c. of hydnocarpus oil containing 4 per cent. of creosote; and when the full dose is reached without local or focal reactions, 1 per cent. sodium hydnocarpate in doses rising from 2 to 10 c.c. is given intravenously, the oil being returned to when a reaction is obtained or the veins become blocked; an alternation of the two methods is best. The drugs may be pushed safely to cause reactions in the first and third stages, but caution is necessary in the active second stage to avoid dangerously severe reactions with spread of the lesions. Considerable experience, such as is only obtainable in the endemic areas, is therefore essential to enable the best results to be obtained. For the severe pain of nerve cases intramuscular injection of 3 or 4 minims of 1 in 1,000 adrenalin chloride is of value, and greatly thickened nerves may be benefited by incision and freeing the nerve from the surrounding tissues. Repeated negative bacteriological examinations, and disappearance of all erythema from the macules, with absence of change in the anæsthesia for six months, are the criteria of the disappearance of all active signs; after which treatment may be stopped and the patient watched for two years. A table is given of 64 cases remaining free from all active signs for one to five years, 36 of whom have been well for three to five years; and it is stated that if all those treated could have been followed up the number would have been four or five times as large, indicating lasting results.

He concludes that in spite of the absence of a certain specific cure "by carrying out treatment along the lines indicated above we can hope for a permanent disappearance of all active signs in almost all patients in whom the disease is recognized early. While in the later stages, although much more prolonged treatment is necessary, very promising results are obtained and many have become entirely better and have remained so for periods of several years." It follows that the treatment of many early cases at clinics, as in Calcutta and many other places in India, "is cutting off to a large extent the bacillary reservoirs which would have served to infect the next generation..... I think we already have in our hands a line of treatment which will aid the rapid disappearance of leprosy from India and from the world, though delay is inevitable, due to the ignorance and backwardness of certain classes of the community."

Sixteen striking photos before and after treatment in different stages are given, which leave no possible doubt of its value in experienced hands.

The next paper by H. W. Wade and C. B. Lara, Chief Pathologist and Chief Physician to the Culion Leper Colony in the Philippines, was communicated and read by L. Rogers, and dealt with the results of the modern treatment in nearly 6,000 cases at Culion and nearly 3,000 at Manila, so is of the greatest importance. After defining a leper they record that the first favourable results of the Mercado mixture intramuscularly, reported by V. G. Heiser, were not altogether confirmed by later experience, as most of the 24 patients who became negative under it apparently relapsed, for only four treated cases were released in 1913 after being negative for two years; the treatment was decidedly heroic. After the introduction of the ethyl ester chaulmoogrates intramuscularly they have been used very extensively, advanced cases averaging 8 years in duration being treated at Culion, and earlier ones at the San Lazaro Hospital at Manila; the number discharged from the later on parole as negative averaged 50 a year during the last five years, and reached 150 in 1925; while 76 more were paroled in the last three years at the Small Cebu detention camp. Among the advanced Culion cases by the beginning of November 1926, 629 negative cases had been obtained, or about 10.5 per cent. of those treated, which all the releases to the end of 1926 will bring up to 800. Moreover, relapses have been few, and are becoming still less frequent with increased experience. From 1913 to 1921, 88 cases were discharged, and between 1922 and 1926, 634, but the former only after being negative for two years, so the figures are not quite comparable.

The authors conclude that the ethyl esters are certainly more effective than the Mercado mixture, and "the modern treatment methods are decidedly superior to the older ones, and seem to be particularly effective in early cases. Though they are admittedly much less effective in well-established advanced cases, the results obtained in the Philippine Islands during the last few years show that a not inconsiderable proportion of such cases (probably 15 to 20 per cent.) can be 'apparently cured' if treated intensively, under proper conditions. This is a noteworthy advance, however discouraging to anyone treating any particular small group of unselected cases. In view of the impressive total, which all 1926 releases will bring to 800 or more, one cannot, we submit, deny the relative effectiveness of present treatment, or its absolute value in properly selected cases. It were quite as correct to deny the value of surgery in cancer. In leprosy, as in cancer, emphasis must be laid on getting the patient early. It is from this point of view that treatment is now revolutionizing anti-leprosy campaign systems."

Isabel Kerr contributed the third paper of the Tropical Diseases Section on the results obtained at the model Dichpali Institution, India; she recorded 17 and 19 per cent. respectively of cases becoming quite negative after treatment in two series of cases each spread over two years, no case that could possibly benefit being refused treatment, and she concluded that "most cases of early leprosy do well, and one can count on a large percentage of successes." She also agrees with Muir that third stage cases improve rapidly, and that with protracted careful treatment second stage cases also improve, 45 to 47 per cent. having been "very much improved" in addition to the recoveries; no less than 63 per cent. of the bacteriologically positive infective cases became non-infective under the treatment. This must result in greatly fewer new cases in the near future.

Robert Cochrane, as the result of a prolonged tour in the East, studying over 10,000 cases, was in agreement with the statements of E. Muir, for of the various treatments he had seen, Muir's creosoted hydnocarpus oil was both the cheapest and most effective remedy. Of 20 cases the speaker had discharged as recovered, none had relapsed eighteen months after the discharge of the last, and all were working as ordinary folk. E. A. O. Travers advocated once more the Chinese treatment with powdered *Hydnocarpus anthelmintica* nut, given orally with a small portion of cannabis indica; by which simple means he had obtained 11.5 per cent. of negative cases at the Kuala Lumpur leprosy institution in the Federated Malay States. The daily doses could be given out to 350 lepers in half an hour. Hasson in a few words reiterated his opinion that his "vaccine was absolutely specific"; the only such claim made in the debate. F. Hall from his experience in charge of the Leper Asylum in Fiji considered that there was no specific treatment for leprosy, and that all treatments producing sensitization or reaction are harmful.

L. Rogers replied for the Tropical Diseases Section, and pointed out that MacLeod's cases, as reported in the tables he showed, were nearly all residual resistant

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

advanced cases in which various treatments had previously been tried without effect; so they were the most unsuitable cases for trial, any want of success being thus explained. The case recently reported by Graham Little as cured by Hasson's vaccine was a temporary exacerbation in a partially immune third stage one, which Muir has shown clears up by itself; so it affords no evidence of the value of the treatment; while Muir had just written to say that he had tried the vaccine sent him by Hasson in a favourable case with complete failure. Rogers then summarized the results recorded in the papers submitted in the Tropical Diseases Section papers, and some other recent trials, in the following table, and he pointed out that the data brought out the facts that in advanced cases only 10 to 20 per cent. became bacteriologically negative. In earlier ones treated at the Kalihi hospital at Honolulu, and at the clinics of Muir and himself at Calcutta for six months or more, 30 to 40 per cent. were apparently cured; the highest rate being 41 per cent. in the only series treated by the soluble sodium salts of the chaulmoogra series of fatty acids intravenously by the speaker. This method had been little used since his early work, on account of the blocking of the veins it often induced; but G. A. Perkins, the Culion expert chemist, had recently stated that it is the most active method, by which effective treatment was first obtained in a large group of cases; the gradual obstruction of the veins appeared to be the main reason against its extensive use at the present time. The speaker was glad to be able to announce that this difficulty had at last been overcome, as an unirritating hydnocarpate of soda had been prepared for him by T. A. Henry, which was painless on subcutaneous and intramuscular injection in the usual 3 per cent. solution, and also nearly unirritating to the veins in a 1 per cent. solution, but quite effective by all three methods; much more so than the ethyl esters in his limited recent experience, while Muir had now adopted it as part of his routine treatment. It had a further great advantage of rapid absorption, and, still more important in the tropics, its cost per dose worked out at about one-twentieth of that of a good ethyl ester. Large amounts had been sent out for trial, and if his experience was confirmed an important practical advance would result.

Since this discussion Muir has written to the reviewer to say that all vein trouble can be avoided, even with a 2 per cent. sodium hydnocarpate solution, by the simple expedient of drawing up about as much blood as the dose, rotating the syringe on its long axis to mix, and injecting the whole; up to 7 c.c. having been given thus with only slight temporary giddiness.

In our issue for April, Dr. Muir deals in general further with the present position with regard to the treatment of leprosy. In a further paper he deals with the difficulties experienced in treatment by blockage of the veins during the treatment of the disease by intravenous injections of hydnocarpus oil, due to endophlebitis. On the whole, intravenous administration of the sodium salts of a special fraction of hydnocarpus oil is followed by less blockage of the veins than is injection of the whole oil. A method is described in which the syringe containing the dose of oil is introduced into the vein, blood aspirated and mixed with the oil, and the combined dose then re-injected. Alternate injection intravenously of sodium hydnocarpus with subcutaneous infiltration with hydnocarpus oil with creosote is advised for general routine treatment.

The same author outlines his suggested treatment of leprosy by the oral administration of huge doses of potassium iodide. Commencing with very small doses, e.g., 1 gr. daily, the dosage is rapidly pushed until the patient is taking up to a daily dose of 240 grs. twice weekly. This leads to marked reactions in the lepromata, swelling and erythema of existing lesions, the appearance of fresh rose-coloured nodules, marked acceleration of the blood sedimentation test, and apparent granulation of the lepra bacilli in the lesions. The ability of the patient to withstand heroic doses of potassium iodide is very remarkable, for the treatment is very free from symptoms of iodism, and in general what is aimed at is a reactionary phase which will help to clear the leprous condition. Further, in suspected cases the

flaring up of the lesions at the commencement of treatment may be of value in assisting diagnosis.

Rat Leprosy.—Along with his study of human leprosy Dr. Muir has been studying the natural leprosy of rats, together with Dr. Henderson and E. Landeman, and their preliminary results have been published during the year. There appears to be a close association between rat leprosy and human leprosy; the former disease is very readily transmissible from rat to rat; and the course of the disease in the rat is a relatively rapid one. After intra-abdominal inoculation of infective material tumour growths occur in the abdominal cavity and are of a granulomatous character, apparently consisting of marked proliferation of the peritoneal endothelial tissue with phagocytosis and multiplication of the bacilli. Fibrosis, caseation, and liquefaction occur in these tumours, and a study of this disease may throw some light upon the pathology of human leprosy.

Miscellanea.—Dr. Muir contributes the following further notes with regard to papers dealing with leprosy during the year 1927.

Efforts to improve the treatment of leprosy are being made in different quarters. Col. R. Row of Bombay continues to obtain improvement in patients by the use of autolysed tubercle bacilli referred to in last year's report, and a paper describing his method read by him before the Far Eastern Congress of Tropical Medicine.

Various other drugs have been advocated by other observers but in many cases the value of the remedy has been estimated by its effect on only one or two cases.

Potassium iodide has been used with remarkably good results in the Calcutta School of Tropical Medicine, both by itself and in combination with hydnocarpus injections, and this treatment has been adopted in several other centres throughout India from which equally satisfactory results are reported.

Iodide has also been found useful in making an early diagnosis in contacts and doubtful cases and in testing the freedom from disease in supposed "cures," in which it frequently shows up unsuspected foci. Some papers were read on this subject at the F. E. A. T. M. Congress and an article appeared in the October number of the *Indian Journal of Medical Research.*

A paper was read at the same Congress by Dr. Donaldson of the Chingleput Leper Settlement on the organisation of that institution, in which he dealt with the diet, treatment, method of keeping records, etc.

An article on the serology of leprosy was contributed by Major Labernadie, his results with the reactions of Metefy and Rubino being found useless in the diagnosis of the disease.

Another paper under the combined authorship of the last mentioned author and Col. Goyon described the frequency of leprosy in Pondicherry and the means adopted to remedy and prevent the disease.

Dr. J. M. Henderson also read a paper on "Some Hæmatological Aspects of the Potassium Iodide Treatment of Leprosy" describing in brief his work both on the hæmocytes and on the various fluid constituents of the blood.

An interesting contribution was given by Major Kirwan on the eye conditions met with in leprosy.

Dr. Raman Lampi mentioned the rapid increase from 1,115 lepers in 1911 to 2,055 in 1921 in the State of Travancore and suggested some probable reasons.

A paper by Muir, Landeman and Wardman described the use of potassium iodide in the diagnosis of the presence of leprosy in the children of leper parents at the children's home in connection with the Purulia Leper Asylum. A large proportion of the children in whom no definite signs of leprosy were discernible showed positive signs of the disease when large doses of iodine were given.

A paper by Muir discussed the value of the erythrocyte sedimentation test in regulating the use of iodides in leprosy, in diagnosis of early cases, and in determining the degree of elimination of the disease from the body.

A small booklet on the *Symptoms, Diagnosis and Treatment of Leprosy* has been contributed by Dr. Robert Cochrane, Medical Advisor to the Mission to Lepers, which abstracts much useful information and appends a useful map of India showing the various leper institutions in the country. Great praise is due to the Mission to Lepers for the splendid work they continue to do all over India in their many asylums and hospitals. In all the more important of these modern treatment has been adopted and first class European and Indian doctors have been appointed who are not only treating those afflicted with leprosy, but are training large numbers of doctors and compounders for this work. Indeed many of those employed in Government and District Board clinics have been trained in the institutions of the Mission.

A paper by Lloyd, Muir and Mitra on the relationship of syphilis and leprosy appeared in the *Indian Journal of Medical Research* for January, 1927. The conclusions arrived at are that a positive Wassermann reaction in leprosy is generally due to accompanying syphilis, but a certain number of false positives are found, the reaction however only being slight. The Kahn precipitation test is recommended as not giving false positives and as being specially suitable for the diagnosis of accompanying syphilis in outlying leprosy dispensaries and hospitals where the elaborate technique of the Wassermann is not available.

A paper by Muir on "The present position of treatment of Leprosy" appeared in the April number of the *Indian Medical Gazette*, abstracted from the *Proc. Roy. Soc. Med.*, shows that while we have as yet no specific for leprosy we have means at hand for dealing effectively with the disease.

PULMONARY TUBERCULOSIS.

Dr. C. Frimodt-Möller, Medical Superintendent of the well known Union Mission Tuberculosis Sanatorium at Madanapalle, S. India (whose first appearance as a regular contributor to this annual review we most cordially welcome), reviews the year as follows:—

Investigating the geographical distribution of some diseases in India, Lieut.-Col. J. W. D. Megaw and J. C. Gupta report that pulmonary tuberculosis is common in 176 districts, rare in 36, and unknown in none, and while undoubtedly very common all over India is specially prevalent in the larger centres of population.

B. N. Gupta and H. K. Dutt using von Pirquet's cuti-reaction in Calcutta find a positive reaction of 32 per cent. for men and 37 per cent. for women, but the total persons examined were only 1,330, far too few a number on which to base any scientific conclusion of tuberculosis incidence in a city with a population of 1¼ millions.

A. C. Ukil of Calcutta, at the Seventh Congress of the F. E. A. T. M. published his results of an investigation into the incidence of tuberculosis in Calcutta and Bengal. After many thousands of examinations he concludes that there is a low degree of bacillisation as well as a low morbidity and mortality from tuberculosis in infancy and childhood, in marked contrast to findings in Europe. This is very striking especially as Dr. M. Kesava Pai and Dr. C. A. Venugopal found in 1926 (*Tubercle*, August 1926) that by the end of the fifth year not less than 80 per cent. of the children were infected in Madras City. B. N. Gupta and H. K. Dutt, who found no positive reaction in 20 children under 5 years of age examined in Calcutta, suggest as an explanation that children, although perhaps more susceptible than adults, when once infected die very quickly and that only a careful investigation of the death-rate of children from tuberculosis will clear the doubts about the incidence of tuberculosis in children in India.

The value of artificial pneumothorax treatment becomes better known in India. Dr. P. T. Patel of Bombay, dealing with this subject, describes an improvised apparatus which is only one more demonstration that an expensive apparatus is not necessary. His remark that no case is too advanced for pneumothorax treatment if only it is one-sided, as long as there are not adhesions which will prevent the compression of the lung, needs guarding against. Experience elsewhere shows, for

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

instance, that abdominal tuberculosis is a contra-indication, as is also laryngeal tuberculosis in many cases. Chronic fibroid disease is mentioned by Dr. Patel as a contra-indication of artificial pneumothorax treatment, but experience in the West, as also seen in Madanapalle, S. India, where this treatment has been used extensively for seven years, shows that it is in such cases that many of the most striking results are obtained.

Dr. M. Kesava Pai of the Tuberculosis Hospital, Madras, deals with the results of artificial pneumothorax treatment in 182 cases. According to his figures 41 per cent. of those patients in whom a good and partial pneumothorax was obtained were discharged as "arrested" and "much improved," that is considering only those patients who have a good prospect for after-life. This is a very good result and compares favourably with those of the West. As both Dr. Patel and Dr. Kesava Pai point out, the treatment is not without its dangers, but neither have had any serious accident, although in Europe there is a death-rate of about one to 1,000 or 1,500 operations.

One of the adjuncts which has recently been to the forefront in the treatment of tuberculosis is sanocrysin. Dr. E. Frimodt-Möller of the U. M. T. Sanatorium in Madanapalle describes (*Indian Medical Gazette*, July 1927) the results of treatment of 80 patients with sanocrysin during a period of two years. He concludes that in sanocrysin we have a drug which is proved to be of great value when properly used in selected cases, although it has its dangers; but these have been much lessened by the treatment now advocated with small doses and long intervals between doses. Dr. M. Kesava Pai, who has treated 43 cases with sanocrysin and 41 with krysolgan, says that sanocrysin is of greater value in the exudative cases, whilst krysolgan seems to have a better effect in the fibrosing cases. Krysolgan is, however, more toxic and produces more unpleasant effects even with small doses (abstract of papers, Seventh Congress, F. E. A. T. M.).

The possibilities of the use of B. C. G. vaccine (Calmette) in India have been dealt with by Dr. A. C. Ukil (Seventh Congress, F. E. A. T. M.), and he foresees a large applicability of this vaccine in the protective inoculation of the vast number of non-immunized people in India, selected by two negative cuti-reactions, whether infant or adult.

Dr. M. Kesava Pai and Dr. K. Venkata Rau, working with the complement-fixation test for tuberculosis, report (*Tubercle*, May 1927) that they have developed a technique by which they get 96 per cent. of positive reactions in clinically tuberculous patients using Besredka's antigen, although they still get 13 per cent. of positives in clinically non-tuberculous subjects. By comparing the von Pirquet and the complement fixation reactions they come to the conclusion that reactivity to tuberculin and complement fixation reactions are due to entirely different substances in the body, as many persons giving a strong von Pirquet reaction are negative by the complement fixation test.

The sedimentation test in India with special reference to tuberculosis has been reported on by Dr. C. Frimodt-Möller and Dr. P. V. Benjamin of Madanapalle (*Tubercle*, November 1927), who studied this reaction in 500 persons, of whom 130 were apparently healthy, 282 tubercular patients, and the rest suffering from diseases other than tuberculosis. They found that the tropical climatic conditions produce a higher rate of sedimentation than in the West and conclude that the test is a valuable help in deciding the question of activity of tuberculosis when considered in due relation to the clinical symptoms of the patients, is of great prognostic value, and should be used as a guiding factor in the treatment, especially in treatment with artificial pneumothorax.

The well known influence of climate on the weight of tuberculous patients has been investigated by Dr. M. Kesava Pai and Dr. C. A. Venugopal (Seventh Congress, F. E. A. T. M.) for patients living in the hot climate of Madras. As elsewhere, there is a fall in the weight curve during the hot dry months, and a rise during the cooler humid months. The gain in weight indicates conditions most conducive to optimum metabolic activity, and loss of weight the opposite.

While considerable progress has been made by individual workers dealing with various aspects of the treatment of tuberculosis, there has hitherto been no combined effort for a determined policy for an organised attack on the disease in India, dealing with the whole problem in its manifold aspects. This would not be so if it were generally recognized that tuberculosis probably is a far more deadly enemy in India than most if not all the so-called tropical diseases, as shown by Sir Leonard Rogers to be the case in Calcutta. In a paper (*Indian Medical Gazette*, June 1927) Dr. C. Frimodt-Möller outlines a policy for a campaign against the disease. No scheme will be fully effective which does not include the three units, equally important, the sanatorium, the hospital and the dispensary; the first in suitable climatic conditions for treatment, research, and training of doctors and the education of the public; the second near all larger towns for treatment and isolation especially of advanced cases; the third chiefly in large centres of population for the detection of cases and the sources of infection. The beginning and the centre of the movement should be at least one efficient sanatorium in each province, but this must be closely followed up by a chain of small inexpensive hospitals and dispensaries. The watchword of the campaign must be education and isolation. The spread of tuberculosis cannot be checked merely by a general improvement of sanitary and social conditions, but will chiefly depend upon the strength and vigor of a direct attack on the disease and its sources.

A review of tuberculosis in India would not be complete without mentioning that there are now signs of an awakening to the seriousness of the situation. A sanatorium is being constructed near Ranchi by the Government of Bihar and Orissa, a Tuberculosis League is planning a sanatorium for the Central Provinces, the National Christian Council of the Punjab is selecting a site for a Union Mission Sanatorium; a similar institution is being begun near Miraj in Bombay Presidency and one small sanatorium by a Mission in South Rajputana. Bombay City and Karachi are now contemplating constructing sanatoria; both the Government of Travancore and a Christian body have schemes for sanatoria under consideration in that state. The Government of Madras is planning a big extension of the Tuberculosis Hospital in Madras in the near future. A small tuberculosis hospital has been established by a Christian body in Rajahmundry, and a Mission hospital for women in Bangalore is in process of conversion into a purely tuberculosis hospital. Finally, existing institutions, such as the Mission sanatorium at Pendra Road in the Central Provinces and at Madar in Rajputana, are working with reconstruction and extensions, and others such as the Union Mission Tuberculosis Sanatorium at Madanapalle and the sanatoria at Bhowali and Almora have increased their accommodation.

A still further paper which perhaps calls for remark is one published in our November issue by C. Krishnamurty on the value of intravenous injections of iodine in tuberculosis. On a study of 15 cases he reports that it is probably not of much use in advanced cases, but that it is of value in early cases—(where the difficulty in testing the value of this, or any other line of treatment, is that so many cases tend towards spontaneous recovery). It is of special value in surgical tuberculosis, whilst sodium morrhuate has proved to be of value in apyrexial cases, and especially when alternated with iodine injections.

DIABETES.

Only one paper published in India during the year calls for review, viz., that by Lieut.-Col. H. W. Acton and Dr. J. P. Bose, on the relationship of the colour of rabbits to their susceptibility to insulin. In rabbits of the same species but of different colours insulin causes a smaller reduction in the blood sugar in the albino than in black rabbits. In black Himalayan rabbits insulin administration produces hypoglycæmia, and the difference in reaction is due to the fact that the albino

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

rabbit has hyperadrenia. The brown Belgian hare responds poorly to injections of adrenalin, and the rise of blood sugar after injection is only slightly above normal. There is a definite association between colour and species with regard to the output of adrenalin from the suprarenal glands. In albino animals this output is high; in melanotic animals it is low. These findings may have some applicability in the insulin treatment of diabetes in races of different colours.

"DEFICIENCY DISEASES," BERI-BERI, EPIDEMIC DROPSY, LATHYRISM.

Here there is a very considerable volume of papers to be dealt with, the most important being the contributions by Lieut.-Col. R. McCarrison, F.R.C.P.

General.—Col. McCarrison deals with the nutritive value of wheat, paddy, and certain other food grains. Whole wheat he finds to be of high nutritive value, whole rice to be of comparatively low value. These differences depend not so much on their proteins as on the content of vitamines and mineral salts. Parboiling, milling, polishing and other processes reduce the nutritive value of rice still further. Thus it is obvious how very poor in nutritive value is the rice diet which is the staple diet of so many millions in India. The superior physique of the races of Northern India is closely correlated with their wheat diet, also with the manner in which these races combine a wheat diet with such "protective foods" as milk, milk products, fruit and green vegetables. The best Indian dietary is one which includes whole wheat, sprouted gram, milk, milk products, and green leafy vegetables, with meat occasionally, as judged by experiments on the omnivorous rat. Every effort should be made to increase the cultivation of wheat in India, and to increase its use in adequate combination with the "protective foods."

The same author has studied the effect of manganese on growth. When ingested in large doses by rats, manganese dioxide exercises a progressively retarding action on growth, but in small doses it markedly stimulates growth; concentrations of the former order —1 part to 12,600 parts of diet—are harmful, concentrations of the latter order—1 part in 617,000—are definitely beneficial. A whole wheat diet provides the almost ideal concentration of these essential manganese salts.

The same author finally deals with what constitute good and bad diets respectively under tropical conditions, this paper being illustrated by a remarkable series of photographs of fed rats. In experimental rats a diet consisting of whole wheat, milk, milk products, sprouted legumes, uncooked vegetables and fruit, with fresh meat occasionally far surpassed in nutritive value one composed of white bread, tea, sugar, margarine, jam, boiled vegetables, and tinned meat to which the usual preservatives had been added. The maladies of which the bad diet is so apt to lay the foundations are lung disease and gastro-intestinal disorders. Faulty and ill-balanced food appear to often be the precursors of such diseases in man. The commoner food preservatives, such as boracic acid, formalin and sulphurous acid, may contribute their share towards the harmful effects of such a faulty diet. The "white-bread-margarine-and-tea diet" is singled out as perhaps the most unsuitable and disease-favouring diet of all.

Beri-beri and Epidemic Dropsy.—Here a considerable number of papers call for review. In our issue for July, Col. Acton and Major Chopra, sum up their experimental work which has now extended over several years on the rice infection theory of epidemic dropsy. There is a close association between epidemic dropsy and the wetting of rice by sudden storms or floods which allow decomposition to start in the rice, such decomposition producing the poisonous pressor bases which, on ingestion by susceptible persons, produce the disease symptoms. The excessive humidity of the monsoon months is also dangerous when rice is stored in stacks and in ill-ventilated godowns. The characteristic diarrhœa of the disease is due to the action of these water-soluble bases causing exfoliation of the mucous membrane of the gut, together with œdema of it. The damage to the mucosa permits intestinal cocci and bacilli to invade the blood-stream, and this gives rise to fever; such cocci are frequently excreted in the urine and can be recovered on culture of a catheter specimen of the patient's urine. The stools in the acute phase of the disease show large numbers of Gram-positive organisms, a condition which is not met with in the stools in health. The "rice bacillus" can be cultivated from the stools of these patients provided that the culture medium contains no bile salts. It is possible that infections may occur of the stomach or duodenum with these organisms —but only under rare and exceptional conditions—and under such rare conditions epidemic dropsy might be transmitted from person to person by fæcal contamination when contact is intimate. This paper is based chiefly upon a study of the 1926 outbreak in Calcutta—an outbreak which was foretold by Col. Acton from the epidemiological conditions present, and which he attributes chiefly to a sudden and unexpected downpour in May at a season of the year when much of the rice for the Howrah godowns was in transit in open boats on the Hooghli. After this, the normal monsoon rainfall was delayed until July 22nd, when there was an abnormally heavy downpour; the incidence curves for epidemic dropsy in Calcutta follow the curves for rainfall at an interval of some 5 to 7 weeks later.

In our issue for May, S. L. Sarcar and B. M. Gupta describe a most interesting outbreak at Sandwip Island situated in the Bay of Bengal about 25 miles from Chittagong. The island is a very fertile one and the inhabitants have a plentiful supply of milk and fresh vegetables, and avitaminosis is not known. All the 25 cases which occurred did so in the town of Sandwip or its environs and were within a radius of 1½ miles of one another. There was tremendously heavy rainfall during August, 1926, especially at the end of the month. The outbreak of epidemic dropsy followed closely after the cessation of this very heavy rainfall, and was in general of a mild but typical character. The gunny bags used for storing rice had come from Barisal—an infected area; most of the rice consumed came from suspected areas and was stored under conditions extremely favourable to rice infection, and the whole outbreak pointed to the importation of either infected rice or of infected rice bags from Barisal, where epidemic dropsy had been raging previously.

Still a further outbreak is recorded from the Fiji Islands in February, 1927, by A. D. Sagayam. The outbreak was in general of mild type, but œdema was a marked symptom and the cases were very slow in clearing up. Rice and dâl are imported into the islands annually in bulk from Calcutta, and in point of time the outbreak followed a few months after the autumn 1926 outbreak in Calcutta. These authors describe the special association of sarcoids—hæmorrhagic new growths of nævi-like character—with the outbreak, a fact which has been further investigated with reference to the Calcutta outbreaks by Col. Acton in the *Indian Journal of Medical Research.* The former writer is strongly inclined to incriminate contaminated mustard oil, and the official medical authorities in the island concluded that the outbreak was due to this cause; but it is clear that the imported rice was not above suspicion.

Still another localised outbreak is recorded by Dr. I. R. Anderson in our issue for February at the U. F. C. Mission in Khulna, Bengal. Here the evidence in favour of person to person infection is very strong indeed. There had previously been no evidence of the existence locally of the disease; it followed immediately after the arrival of infected persons from Calcutta; there was no apparent connection between the rice supply and the incidence of the disease, and where an explosive outbreak might have been expected if the local rice supplies were infected, none occurred.

It is difficult to sum up the evidence afforded by these papers, but Col. Acton's work and views appear to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

678471

afford a clue to the entire riddle. Normally, he claims, the outbreaks are due to rice stored under damp, hot, and humid conditions, which becomes infected with the "rice bacillus" (such infected rice being easily detected by a simple water test, or still simpler glycerine test); the infection produces poisonous pressor bases in the infected rice, and on ingestion of this poisonous rice *in susceptible persons*—i.e., in those whose normal hepatic and endocrine defence mechanism has been lowered—these bases, as has been proved in experimental animals, can produce all the symptoms of epidemic dropsy. On the other hand the "rice bacillus" apparently can occasionally and exceptionally establish itself in the intestinal tract of certain persons, when person to person infection may occur, via the contaminative method. Control of rice storage conditions should lead to the prevention of the disease, which has little or nothing to do with avitaminosis.

Dr. A. E. Coyne of Kistna gives a general account of the symptomatology of beri-beri and its treatment, especially advocating the use of marmite and tea made from rice polishings. A vegetable diet is also added and the patients taken completely off rice if possible. Massage is mentioned as of special value in the control of the pains in the limbs and for persistent paresis. C. Ray has investigated the general and biochemical blood picture in epidemic dropsy. Usually there is leucocytosis of mild degree, and as judged by hæmatocrite readings a definitely hydræmic condition of the blood. The blood coagulation time is about normal, but the total nitrogen and protein values are much below normal. Indican is commonly present in the urine. Retention of chlorides is associated with the œdema of the disease, and this author again draws attention to the association of the disease with new angiomatous swellings on the skin. The blood calcium and cholesterol content are lowered, and the globulin content is markedly increased, together with diminution of the albumin content of the blood.

Lathyrism has been the subject of two papers. Lieut.-Col. T. C. McCombie Young has been studying the disease in its endemic home in Central India under the auspices of the Indian Research Fund Association, and the summary of his paper is a valuable one in summing up our present knowledge of the disease. When the legume *Lathyrus sativus* (*matra* or *khesari dâl*) which is generally sown with the wheat as a precaution in case of a dry year and the failure of the wheat to germinate, is the predominant article in the diet, then lathyrism becomes prevalent. Famine years, associated with partial starvation and avitaminosis, are years particularly favourable for lathyrism. A community suffering from lathyrism is also in a state of marked nutritional instability due to lack of the protective food substances, notably vitamine fat-soluble A. Night blindness is also notoriously prevalent in company with lathyrism. In general deficiency diseases and lathyrism suggest significant resemblances. In villages where the Mohamedans eat as much *khesari dâl* as their Hindu neighbours, but supplement their diet with other substances, lathyrism is unknown. Lack of milk and of green vegetables may be contributory factors. To prohibit the cultivation of *khesari dâl* is impossible, since the villagers rely on it in seasons of scarcity. This paper is a very valuable one in its general and impartial summing up of the situation; and it is obvious that either a food-intoxication or a food-deficiency theory will meet the facts adduced. It has a good bibliography and is illustrated with useful photographs which show the typical attitudes assumed in different stages of the disease.

In our issue for April, Major L. H. L. Mackenzie gives notes on some cases of suspected lathyrism which he encountered in the Gilgit Agency. Males only are affected, and the disease is locally attributed to eating *gharash* (the local name for *Lathyrus sativus*). Grain grown on newly cultivated areas is said to be especially poisonous, and not that grown on previously tilled fields. The sex incidence—attacking males only, of all ages—appears to be peculiar.

GOITRE.

Here of course the chief contributor is Lieut.-Col. R. McCarrison, F.R.C.P., whose principal papers have been published in the *Indian Journal of Medical Research*, with summaries of them in the *Lancet* and *British Medical Journal*. He records the production in experimental rats of a new type of goitre which is unrelated in its origin to iodine deficiency, whilst ætiologically, pathologically, and epidemiologically it differs from the chronic hypertrophic or adeno-parenchymatous type of endemic goitre and from the diffuse goitre of endemic origin. The basal factor in its causation is a diet containing more than 60 per cent. of white flour or of vitamine-poor carbohydrate, 20 per cent. or less of protein, with fats and inorganic salts (including iodine) in adequate amounts, but no green vegetables or fruit. This type of goitre is associated with intense secretory activity which ultimately leads to exhaustion of the secretory epithelium and its replacement by non-secretory and fibrotic elements. These changes may indeed be present without any alteration in the size of the thyroid gland. Sporadically, this type of goitre may be found to occur amongst white flour eating peoples, and its subjects will be prone to develop Graves' disease after such influences as fright, mental worry, lactation, and infectious diseases, whilst those in the retrogressive stages of the disease may show myxœdema. The administration of iodine is not expected to prevent the onset of this type of goitre, but a well-balanced vitamine-rich diet should.

The same author details the further history of goitre at the Lawrence Royal Military School, Sanawar, Simla Hills—a continuation of his former studies at that School. His previous claims were that the goitre at this school was due to bacterial contamination of the drinking water supply to the school and that the disease could be checked by the introduction of a chemically and bacteriologically pure water supply. Such a new water supply was provided in 1918. The result is claimed to have been that goitre, which has been endemic at Sanawar for 70 years, has now virtually disappeared within three years of the introduction of the new supply. The soil in Sanawar is poor in iodine, also its water supply. The former water supply actually contained more iodine than the present supply, and the present improvement cannot therefore be attributed to an increased iodine content in it. It is apparently the bacteriological purity of the new supply which is responsible.

Col. McCarrison, with Major Clive Newcomb, Mr. B. Viswanath, and Dr. R. V. Norris, D.SC., have also investigated the relationship of endemic goitre to the iodine content of soils and of drinking waters. This refers only to the classical type of goitre, parenchymatous goitre. They conclude that in sea coast, submontane and montane (ex-Himalayan) regions in India where goitre is unknown the freedom of these areas from goitre bears no relationship to the iodine content of the soil. Incipient goitres occur in areas where the iodine content is high. In Himalayan areas where the adeno-parenchymatous type of goitre is of high incidence the iodine content of the soil is in general very low. The water supply of a given place may contain an appreciable amount of iodine and yet goitre be endemic therein. The substitution of a bacteriologically pure water supply in place of an impure one has caused the rapid disappearance of goitre, although the new water supply contained less iodine than the former one. On the other hand, the disease is less likely to arise in iodine-rich localities in Southern India than in iodine-poor localities in Himalayan India. The essential cause of this type of endemic goitre, it is claimed, is unhygienic conditions of the life of the people, and especially impurity of their drinking water supply. A deficiency of iodine under such conditions is favourable to the development of the disease.

By way of treatment of goitre Sub-assistant Surgeon A. V. J. Reddi claims good results after intravenous injections of sodium iodide. Only five cases are cited, but the results bear out the contention of a former

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

contributor—Lieut. E. A. Davies, I.M.D.—that this method is one of the readiest and most efficient available for the treatment in general of goitre.

NERVOUS AND MENTAL DISEASES.

Perhaps the most interesting paper of the year is that by Lieut.-Col. H. W. Acton on *neurasthenia* in the tropics. The chief underlying factor in these cases he believes to be depression of the endocrine system, which may follow acute fevers, chronic intoxications, or the absorption of toxins from an intestine ulcerated by the action of Flexner's bacillus, or more rarely *Entamœba histolytica*. In the last group of cases the entire bacterial flora of the gut seems to show a marked departure from normal. Heat and humidity play their part and the ordinary European dress is unsuitable (in the male sex) for tropical conditions, whilst the Oriental is wiser than the Westerner in keeping to two meals a day taken in the morning and evening. Lack of ventilation owing to houses being shut up to keep out the heat, and the poor quality of the food in Indian bazaars are further factors, whilst some take too much exercise and others too little. The earliest symptoms are those of hypothyroidism, with lowering of the basal metabolism, a dry skin and loss of hair. With depression of the adrenals goes diminution in the tone of the whole involuntary muscle system, and often an increase in the normal pigmentation. Depression of the genital system leads to loss of sexual power and introspection. By degrees the patient passes into a condition of profound neurasthenia, showing introspectiveness, morbid anxiety, dread of the development of some fatal disease, and even actual phobias. The treatment of these cases is not easy, but the first essential is to secure the patient's confidence and co-operation; such patients are really and genuinely ill, and it is no good labelling them "neurotics." The case must be patiently and fully investigated, and the exciting and predisposing cause found out. Glandular therapy is of special value, but each case must be worked out on its own merits. Chronic bacillary or amœbic infection of the gut, if present, must be treated. In the discussion which followed Col. Acton's paper a variety of views was expressed, several speakers dwelling upon the sex aspects of neurasthenia, and others upon trauma and surgical operations as exciting factors.

Dr. F. H. B. Norrie records a very remarkable instance of cure of spastic paraplegia by induction of benign tertian malaria. The patient on admission had been unable to stand or walk for six months, and had a history of old standing syphilis. He was treated with "bismostab" and later by induction of malaria. Before dismissal he could walk a mile without sitting down and was in robust health and strength. The author attributes the recovery rather to the induced malaria than to the bismuth injections.

Major T. A. Hughes and Mr. D. L. Shrivastava, M.SC., have investigated the carbohydrate tolerance in two cases of muscular dystrophy. A high fasting degree of blood sugar was found, and defective power of storing glucose; the renal threshold to glucose was high in both cases, and it is concluded that the diminished glucose tolerance is due to the wasting and poor blood supply of the voluntary muscles.

Dr. W. Nunan of Bombay discusses *mental suggestion* as a remedial agent. He details cases of skin disease, of melancholia, of insomnia, of drunkenness, and of bad behaviour and kleptomania cured by suggestion, and makes a vigorous plea for independent investigation of the value of the method. He complains of the attitude of those who condemn suggestion without investigating its real value, to which he admits there are bounds. In a further contribution he complains of the barbarous methods of treatment of children for eneuresis, and emphasises that mental suggestion is of special value in such cases, even in adults in whom the habit had been ingrained since childhood.

Mental Diseases.—Lieut. O. A. R. Berkeley-Hill writes of new methods of therapy in mental diseases. The first is the induction of aseptic meningitis in cases of dementia præcox by intrathecal injection of sterile horse serum. Six patients were treated, but on the whole the results were disappointing. A second treatment tried was that of dementia præcox, melancholia, and imbecility by intensive courses of bromides. Doses up to 210 grains a day are given for a few days, the patients being under continuous observation, fed when possible and carefully nursed. Four cases were tried and all markedly improved. A third line of treatment tried was the artificial induction of malaria in cases of confusional insanity, general paralysis, manic-depressive insanity, dementia præcox, and anergic stupor. The last case was particularly unfortunate, for the patient was injected (twice) with bloods which were believed to contain only *Plasmodium vivax*, but died from a mixed infection with benign and malignant tertian malaria. The results on the whole varied widely; a patient with acute confusional insanity suddenly and melodramatically regained his mental health; a patient with general paralysis was completely cured; as was also a case of polyneuritic psychosis and one of dementia præcox; in other cases the induction of malaria failed to improve the patients' mental state. A fourth treatment tried was endocrine therapy together with administration of lymphoid substance in cases of asthenic dementia and insanity; three out of four patients treated showed marked improvement and two of them are now back at work and apparently cured. It is clear that the old rule of thumb methods of "treatment" of mental diseases are a matter of the past and that new lines of therapy are under investigation and may yield the happiest of results.

MEDICAL EDUCATION IN INDIA.

The thorny subject of medical education in India has been much discussed during the year, owing to the publication of Sir Norman Walker's report to the General Medical Council, and was the subject of an editorial in our issue for June by Col. Megaw. Much of Sir Norman's report is encouraging, especially his references to the splendid teaching in some of the Indian eye hospitals, and his friendly criticisms of our shortcomings will, we hope, be received in the same spirit in which they were made. Fundamentally, whilst medical education in India is on the whole good, there are three very adverse factors:—(*a*) The want of a sufficient basic general knowledge among the students on which to build. To some extent, of course, this difficulty is due to the fact that teaching has to be in a foreign language; yet there is no getting away from this difficulty, since textbooks do not exist in the vernaculars, and even if they did, it would be necessary to teach in half a dozen different tongues; hence English has to be the medium of instruction. (*b*) The want of uniformity among the syllabuses and their unfortunate copying of out of date and inappropriate syllabuses much more suitable for medicine in temperate zones; "the teaching in medicine, surgery, and midwifery is on lines similar to those followed by the medical schools in Great Britain twenty years ago." (*c*) To these we would add the fact that the teachers are often not in reality whole time men, but that a large part of their time is taken up with private practice. This may be unavoidable, but it seems to us to be especially unfortunate. It is difficult to see how matters are to be reformed, but we would agree with the *Statesman* that perhaps too much attention has been paid in this country to secondary education and too little to primary education. Efforts should be made to raise the general standard of knowledge of the students admitted so that they shall be receptive of new knowledge and interest, rather than haunted by the examination spectre. A well known Indian politician recently asked the reviewer "How is it that so many Bengalis make fortunes in the practice of the Law, and so few in the practice of Medicine?" The writer has long pondered on what should be the answer to this question, without finding one, so may take this opportunity of passing it on to his readers. The legal mind has been defined by a cynic as "that which comes to the most unforeseen conclusion by the most circuitous route." Is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

it that the dusty unrealities of the Law appeal more to some Indian minds than the vivid realities of medical practice; or is it that the Indian population is far more willing to pay for legal advice than for medical treatment?

Allied, perhaps, to the question of medical education in India is the subject of the *mofussil* dispensary, dealt with in an editorial in our issue for December. In our issue for January, Col. Proctor had certain criticisms to make, not so much of the men in charge of these *mofussil* dispensaries, as of the system which starves them of funds and adequate facilities and tends thereby to bring modern scientific medicine into disrepute with the population of India. To this Sub-assistant Surgeon, A. K. Bhattacharya replies vigorously, and we have attempted to sum up the discussion in our editorial. The position is an exceedingly difficult one, and one would hesitate to claim that the policy of opening up numerous minor medical schools in the *mofussil* districts is going to solve it. We understand, for instance, that in the town of Burdwan alone there are 17 Calcutta M.Bs. engaged in private practice, and about 30 other medical practitioners of lower qualifications. That India needs as many qualified medical practitioners as she can get is a truism, and the number of applicants for admission to the big medical schools and colleges is some ten times their teaching capacity, but even so the qualified men often find it extremely hard to make a livelihood.

The most urgent preliminary measure would appear to be the necessity for the creation of an all-India General Medical Council to raise and maintain the standard of medical education and examination in all the Provinces, but we hope that, should such a Council come into being, it will act not as a merely judicial body, but will do something to assist as well as to judge the legitimate and qualified medical practitioner.

MISCELLANEOUS.

In addition to the above subjects a number of miscellaneous papers call for review. In our issue for June, Lieut.-Col. J. W. D. Megaw and J. C. Gupta discuss the geographical distribution of some of the diseases of India; typhoid fever is common all over the country; relapsing fever is shown to have a much wider distribution than was previously suspected; whilst the incidence of the dysenteries is surprisingly low. The maps which illustrate this article are made out in accordance with the replies received to a general questionnaire sent out all over India, and, whilst the information therein recorded is undoubtedly incomplete and sometimes perhaps inaccurate, the whole paper is a very valuable one and gives us something to go upon. In any general campaign against the more important tropical diseases in this country a knowledge of the geographical distribution of the diseases concerned is clearly of primary importance.

Dr. Gordon Roberts gives an interesting account in our issue for February of the well known Welsh Mission Hospital at Shillong, and of its work. This splendid hospital is one of the finest and best run in India and shows how valuable to this country is the work carried out quietly and unostentatiously by the medical missions in India.

The medicinal treatment of *gastric and duodenal ulcers* is dealt with by Major H. Hingston. He emphasises the invariable presence of pain as a diagnostic symptom, of a history of melæna on cross examination of the patient, of slight abdominal rigidity and of abdominal tenderness on deep pressure. *X*-rays and a fractional test meal are valuable aids in diagnosis, though not often available. By way of treatment a modified Sippy programme is detailed which is less laborious to carry out than the original one, and which seems to give good results. He is of opinion that medicinal treatment of the condition is palliative, rather than curative, and that "surgery seems to be the only hope."

In our issue for December, Noor Husain records a very interesting case of extensive scalding in a young child followed by acute abdominal symptoms on the ninth day, which proved fatal on the twelfth day. The case appears to be one of those rare cases of duodenal ulceration following after a severe burn or scald.

Anæmia has been the subject of two papers published during the year. Dr. P. V. Gharpure deals with the pathology of pernicious anæmia as studied in a series of post-mortem examinations at the Grant Medical College, Bombay. The pathological picture in general is a constant one and varies only degree. The peripheral blood shows a few normoblasts, megaloblasts, and anisocytosis; the bone-marrow shows overgrowth and megaloblastic reaction, whilst overgrowth absorbs the compact bone. The heart, kidney, and liver show fatty changes; the spleen is fibrosed; the intestine is pale and smooth, and small petechial hæmorrhages are seen in almost all the organs. Capt. P. N. Basu analyses the causation and blood picture in cases of anæmia among the troops in Bombay. He finds a marked deficiency of free HCl to be constantly present on gastric analysis, whilst there is a disturbance of the normal ratio of neutral fat to free fatty acids in the stools. The fragility of the red blood corpuscles is about normal, and whilst the blood calcium content is lower than the usually accepted figures for Europeans, it is not markedly different from that for healthy Indians. Bacteriological examination of the stools showed the presence of large numbers of putrefactive and fermentative organisms, which proved to be pathogenic in type on inoculation into laboratory animals. The enquiry was closed down prematurely, but the indications are that auto-intoxication from the intestine may play an important part in the causation of idiopathic anæmia in the tropics.

Cystitis.—G. Panja and K. Banerjee have been investigating the bacteriology of cystitis. Contrary to the usually accepted belief, they find that the *Bacillus coli communis* is not the organism most frequently present. Both lactose and non-lactose-fermenters were isolated, and all organisms present were of intestinal type. These may enter the blood-serum either in septicæmic states and be excreted in the urine without producing cystitis, as is so commonly the case in the enteric fevers; or may enter the blood-stream through ulcers in the gut, and be excreted in the urine, as is commonly the case in epidemic dropsy, chronic dysentery of whatever type, and "mucous colitis." In the female, further invasion may take place from the urethra. Streptococci are not infrequently present in cases of chronic dysentery and in epidemic dropsy. Autogenous vaccines and treatment of the ulceration in the intestine are often followed by very good results.

Major T. A. Hughes and Mr. D. L. Shrivastava have made a study of *renal œdema*. Sixteen chronic cases were observed and determinations made of the capacity of the kidneys to concentrate urea and chlorides, of the chloride, urea and cholesterol content of the blood, of the ability of the kidney to excrete water, and of the urinary changes. In two cases primary retention of water seems to have been the cause of the œdema, in the other cases the dropsy seems to have been of pre-renal origin, due to abnormal permeability of the capillary endothelium to water and salt. In one case of pure nephrosis and in one of nephrosis with very early nephritic changes considerable improvement was effected by a high protein diet and large doses of thyroid extract. The same authors have studied *post-malarial cirrhosis of the liver*. The clinical picture in some of these cases strongly resembles that of alcoholic cirrhosis, but alcohol can be excluded as a contributory factor in many cases. In the early phases, there is increased fragility of the red blood cells in hypotonic saline solutions; in advanced cases this fragility disappears and may be replaced by increased corpuscular resistance. Splenomegaly accompanies the hepatic cirrhosis, and perhaps the hypertrophy and multiplication of the reticulo-endothelial tissue is an expression of immunity acquired to repeated attacks of malaria.

Snake Bite.—B. N. Rao pleads for a more extensive use of antivenene in cases of snake bite, giving details of two cases in which doses of 40 c.c. appeared to be of value. The biting snakes were not identified, but in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

second case a previous fatality had occurred from a bite from what was apparently the same species of snake.

A special feature of the year with regard to tropical medicine was the publication of *The Life and Work of Sir Patrick Manson* by Dr. Manson-Bahr and Lieut.-Col. A. Alcock, I.M.S. (retd.). This has been reviewed in our columns; as also in the *Tropical Diseases Bulletin* by Dr. Andrew Balfour. Dr. Balfour notes that the book hardly gives that living picture of Manson which all of his former students cherish, "yet it would be ungracious and unfair to find fault in any way with the fine tribute the joint authors have paid to Manson's memory because this rare and elusive gift is not in evidence. They have given of their best and have produced, not only a sound and interesting book, but a fitting testimony in text and illustration to one who did much for Science and even more for humanity."

SURGERY IN THE TROPICS.

Lieut.-Col. W. L. Harnett, F.R.C.S., very kindly contributes the following review:—

The surgical section of the Far Eastern Association of Tropical Medicine produced a disappointingly small array of papers, but several of these dealt with matters of great importance. Major-General Hooton, I.M.S., read a paper on the choice of operation for vesical calculus in which he deplored the increasing tendency to substitute suprapubic lithotomy for litholapaxy. The speaker attributed this to the trend of current teaching in Europe and America, but the subsequent discussion showed considerable difference of opinion as to the causes of the change in practice. All the speakers agreed that litholapaxy is the best operation in suitable cases, but considerable experience is necessary in selecting the right cases and considerable practice in the actual performance of the operation. Litholapaxy is a dangerous operation in cases where there is a co-existing enlargement of the prostate, or where the kidneys are gravely damaged by chronic pyelonephritis, to mention only two of the common causes of trouble. The increasing exactitude of the diagnosis of urinary disease by means of the cystoscope, by kidney function tests and by radiographs has tended to reduce the number of litholapaxies, by eliminating cases which are now recognised as bad risks for this class of operation. The reviewer is of opinion from a study of recent literature and from observation of the practice in genito-urinary clinics in London and Paris that there has been no real change in the opinions of urologists, the change is in the increased precision of preoperative diagnosis. As regards general surgeons it is difficult to generalise, as the recent increase of genito-urinary special departments is gradually transferring all these cases in Europe to the hands of specialists. The necessity for considerable practice in order to master the technique of the operation is the real determining factor in India, and it is for this reason that litholapaxy is not so popular in Bengal as it is in the Punjab, where the cases are so numerous that the operation is often done in the out-patient department, a proceeding which one would think risky, but apparently it has the approval of the patients. The high cost of the necessary instruments for litholapaxy, when compared with the few simple instruments required for the suprapubic operation, is another point in a country where the cost of equipment has to be cut down to the bare minimum on which a hospital can be kept going at all, and where the layman and not the medical man has the last word in the matter of financial provision. The question is one which has been brought up repeatedly in the columns of the *Indian Medical Gazette* during the past few years and General Hooton's paper is welcome for the help it may afford in drawing attention to a retrograde movement, whether his diagnosis of the cause of it be correct or not.

Lieut.-Col. Sir Frank Connor opened a discussion on filariasis, in which he stressed the need for research on the treatment of the early stages of the disease. He was followed by Dr. K. K. Chatterjee who dealt with the pathological aspect of the question, but none of the speakers who followed had much that was new to say. The subject is in a stagnant condition at present, but work is in progress at the Calcutta School of Tropical Medicine and we have no doubt that the next few years will see some advance.

The paper on gastric and duodenal ulcer which was down in the name of Dr. Wanless was replaced by one by Col. Bradfield. The Madras General Hospital has acquired a great reputation in this field and the figures which Col. Bradfield brought forward were very striking, especially when compared with the figures showing the small number of these cases treated surgically before he started work. In order to get the cases he had to go to the out-patient department himself and see the cases of "dyspepsia" being treated there, but once the initial inertia was overcome, a steady and increasing stream of cases began to come clamouring for operation. In a recent number of this journal Major Hingston has drawn attention to the great prevalence of this disease in Bengal and the wide field lying waiting for surgeons. The subsequent discussion followed the usual lines of a surgical meeting, questions of technique, after-treatment and the choice of cases for resection being much to the fore, but it transpired that what Col. Bradfield really wished was to initiate a discussion on the causation of gastric ulcer and it had been intended that Col. McCarrison should explain his views on the rôle of nutritional deficiency in its causation, but unfortunately he was occupied elsewhere.

Dr. K. K. Chatterjee brought forward some examples of chronic peritonitis due to amœbiasis and Capt. Nigam showed on the cinematograph the steps of his operation for drainage of epidemic ascites by means of a tube of fascia lata, that wonderful tissue of amazing vitality, whose surgical possibilities are only just beginning to be exploited.

Turning now to the papers published during the year, we have first a short but important paper by Capt. Hayes in which he attempts to grade liver abscesses according to size, laying down rough rules for treatment by emetine alone, aspiration and emetine, or siphon drainage on this basis. Useful as this method is, it must not be forgotten that there are grades of virulence in hepatic amœbiasis as well as in other infections and that size of the liver is not the only criterion. Lieut.-Col. Roberts contributes useful papers on some common injuries of the knee-joint and on infections of the kidneys, in which he advises nephrectomy for acute fulminating pyelonephritis when unilateral, but does not stress the care which must be taken to ascertain first that the infection is unilateral before this advice is followed. Kelyanvala has a paper on the treatment of ascites by permanent drainage into the subcutaneous tissues by means of silver tubes. One case only is quoted but this subject was dealt with in the surgical section at the Far Eastern Association of Tropical Medicine and it would appear that these cases are more amenable to surgical treatment than the ordinary form of ascites and cirrhosis met with in Europe. Dr. Panja's paper on the bacteriology of cystitis is unsatisfactory, because we are not told whether the cases were primary or secondary to kidney infection and whether they complicated any other lesion of the genito-urinary tract. Capt. Barret contributes a short note on spurs of bones commonly met with in radiological practice with some useful illustrations. Dr. Frimodt-Möller's paper on tuberculosis dispensaries and sanatoria, though primarily of medical interest, should be read by all for its emphatic condemnation of the waste of money which results from the multiplication of tuberculosis dispensaries in large towns and the account of the results which may be achieved at comparatively small cost when the problem is tackled in the right way. Major De's report on the post-mortem examinations of the bodies of the victims of the Calcutta riots is of great interest, on account of the high percentage of penetrating stab wounds which injured an important organ and the numerous cases in which multiple injuries were found and in which surgical treatment was hopeless. In one curious case the only lesion was a small wound behind the mastoid, but the spinal canal had been opened and the vertebral artery

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

divided. Major Hance has a short paper on the value of sigmoidoscopy in the diagnosis of chronic dysentery in cases where the laboratory findings are negative and to check the results of treatment. This valuable method which owes much to the advocacy of Manson-Bahr is not yet sufficiently made use of out here. Dr. Chakravarti's case of periaterial sympathectomy in the *Calcutta Medical Journal* is interesting, but the case would appear to have progressed too far to permit of this method of treatment, as is generally the case in this country. Lieut.-Col. Harnett's paper on the walking caliper splint draws attention to a most useful piece of apparatus as yet hardly known out here.

We have commented before on the tendency of contributors to write up cases which they would find to be commonplace if they would only consult some book used by students for the higher examinations before writing. Instances this year are reports on cases of excision of the elbow, parovarian cysts, and liver abscess.

Of case reports there is such a plethora that the task of sorting them out is very difficult. Christian's account of a successful operation for a fibroneuroma of the cauda equina in the hospital at Bangkok easily takes first place. Reports of cases of recovery after abdominal wounds are numerous. Drs. Varma, and Abdul Samad Khan amongst others describe cases which illustrate the wonderful recuperative powers of the peritoneum, in Dr. Khan's case late intestinal obstruction necessitated a secondary operation. A remarkable case of double intussusception, one of the ordinary ileo-cæcal type and the other a retrograde colic one which recovered after operation is recorded by Pillai. Of foreign bodies there are numerous instances, the best being the case recorded by Dr. Jwala Prosad of the removal of a mass of raw caoutchouc from the stomach of a patient who had been taking the latex of the banyan tree for two years as a tonic. Dr. Norrie removed a pice which had dwelt in the œsophagus for two months and Dr. Sharma an iron ring $3\frac{1}{2}'' \times \frac{3}{4}''$ which had to be removed from the penis by means of a file. A scorpion is an unusual inhabitual of the ear, but Dr. Seshachalan records an instance of the removal of one. Dr. Hukam Chand Gupta's case of gangrene and death following the crushing of a stone impacted at the neck of a bladder shows the unwisdom of performing any major urinary operation in the presence of acute or chronic retention; the latter should first be relieved and the major operation performed later when the acute condition has quieted down. Eleven stones in the bladder as recorded by Mamabud Din is very remarkable. Other unusual conditions are Major Vaidya's case of cyst of the mesentery, Dr. Chatterjee's case of universal surgical emphysema following a fractured rib, described in a most amusing manner, Dr. Reddi's successful treatment of goitre by intravenous injections of sodium iodide, Dr. Bhaskara Ram's use of subcutaneous injections of a 25 per cent. solution of magnesium sulphate in cases of tetanus where serum is not available, Major Mukherjee's case of bony ankylosis between the jaws in a case of cancrum oris, and Dr. Dutt Gupta's case of cirsoid aneurysm of the dorsalis pedis artery. Altogether a good year well above the average in the output of surgical literature.

Apart from Col. Harnett's review above, certain other papers perhaps call for review. Amongst these—although perhaps scarcely surgical in aspect—is Col. McCarrison's series of papers on the experimental production of *vesical calculus* in rats fed on a certain diet, published *in extenso* in the *Indian Journal of Medical Research*, and abstracted in the *British Medical Journal*. These papers continue work first begun by the Japanese observers. In his first paper Col. McCarrison shows that stone-in-the-bladder resulted in rats fed on diets commonly used by man, the faults of which were: (*a*) absence of proteins of animal origin; (*b*) relative deficiency in vitamine A; (*c*) excess of earthy phosphates; and (*d*) a possible toxic action on the urinary tract of one ingredient in the diet. In his second paper the results published in the first were confirmed, and in general the conclusion is reached that a diet consisting of whole wheat flour, linseed meal, cornflour, salt, and calcium phosphate is very potent in causing stone-in-the-bladder and its sequelæ. The main faults of this diet are its high content of cereal foods and phosphates and its deficiency in vitamine A. In these respects the diet approaches in quality that used by the inhabitants of those areas in Northern Indian where vesical calculus is common. In his third paper Col. McCarrison finds that the addition of whole milk, in the proportion of 2|3rds oz. per rat daily to the former diet capable of producing urolithiasis in 50 per cent. of young rats, completely prevented the development of phosphatic calculi. These results may be fraught with tremendous importance, for it is shown that suitable dieting may prevent the development of vesical calculus, and the addition of fresh milk to the dietaries in Northern India should not be impossible.

Carcinoma is a subject which has attracted some attention in India during the year. Lieut.-Col. J. A. Shorten gave a most interesting account of a visit to the Curie Foundation in Paris and of the successful treatment there of cases of malignant disease of the cervix uteri, tongue, and larynx by exposure to massive doses of radium. The percentage of inoperable cases cured of carcinoma of the cervix has risen from 5 per cent. in 1919 to 25 per cent. in 1924, and of operable cases from 22 per cent. to 71 per cent. The latter figures are very striking when one considers the seriousness of the condition. Radium therapy, however, is a two-edged sword and if employed in insufficient quantities by inexperienced persons may do more harm than good. Dr. Gharpure writes on the incidence of primary carcinoma of the liver, as studied at post-mortems at the Grant Medical College, Bombay; whilst many cases diagnosed as being primary cancer of the liver are in reality secondary to smaller growths elsewhere which are easily overlooked, yet—in conformity with Sir Leonard Rogers' findings for Calcutta—he makes out a strong case for regarding primary carcinoma of the liver as being definitely more common in India than in Europe. R. P. Ghosh records a case of rodent ulcer of the face cured by three injections of "Collosol" selenium.

With reference to *abdominal surgery* a few cases reported in journals outside India by workers in this country call for comment. Capt. R. H. C. Pryn, R.A.M.C., records the case of a British soldier admitted to hospital with an enteric-like fever. The *B. pyocyaneus* was isolated from the blood-stream, however, and sudden perforation of the ileum occurred. This proved fatal in spite of immediate operation, five days later, and at autopsy the *B. pyocyaneus* was isolated from the intestinal contents, spleen, and the lymph nodes. A second patient was a British soldier admitted with typhoid fever, and *B. typhosus* isolated on blood culture. The fever relapsed and perforation ensued. He recovered after immediate operation, and Capt. Pryn writes of the special value of morphia injections after operation in such cases. In a third case of typical enteric fever, without perforation, the *B. pyocyaneus* was isolated in blood culture; and it would seem that—like the streptococcus, which is a not infrequent invader of the blood-stream through typhoid ulcers in the gut—the *B. pyocyaneus* may also play a similar rôle.

Lieut.-Col. W. F. Brayne and Dr. A. I. Simon record an interesting case of pedunculated submucous fibromyoma of the stomach. The patient, an Anglo-Indian female, aged 32, was suspected to be suffering from gastric ulcer, with hæmoptysis and melæna. The tumour was discovered and removed at operation, and the diagnosis of fibromyoma made by Lieut.-Col. J. Taylor of the Pasteur Institute, Rangoon. Dr. J. D. Dhruv, M.S., F.R.C.S. (Eng.), records two interesting cases of *acute hæmorrhagic pancreatitis* in the *Lancet*; the first patient presented rather vague abdominal symptoms with pain and tenderness and fever and died on the 7th day; the condition was only found at autopsy. In the second patient the onset of symptoms was so gradual that surgical treatment was only advised on the 7th day,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and only permitted by the relatives four days later. At operation acute hæmorrhagic pancreatitis was found, and the patient did not survive the shock of operation. Both cases illustrate the fact that the onset of acute hæmorrhagic pancreatitis may be insidious and slow, and not always sudden and dramatic.

S. R. Moolgavkar attributes the formation of white clot within aneurysmal sacs to stagnation of a small portion of the blood within the sac which is not affected by the systole-diastole of the heart. Major M. Morris, R.A.M.C., records an interesting case of aneurysm of the posterior tibial artery following a fracture of both bones of the leg in an Indian sowar. The aneurysm was first noticed seven weeks after the fracture had been set and occurred in the middle of the calf, just at the site of the fracture. At operation the sac of an arterio-venous aneurysm was found adherent anteriorly to the periosteum; it had hollowed out the tibia into a cup-shaped depression. Operation was followed by completely successful results. The author notes that at first he thought that the aneurysm might be the result of direct violence applied to the part, but the fracture was the result of indirect violence and due to the patient catching his foot in an irregularity in the ground and falling.

Cases of acute glossitis with sudden onset are recorded by A. B. de Castro and S. K. Bhave, whilst Hyderali Khan describes two curious cases of ankyloglossia or extensive adhesion of the tongue. The first patient was an Indian female of 48 who had been treated with very large doses of mercurial salts by a hakim; acute salivation and glossitis had followed and the tongue was finally fixed in a position slightly protruding from the mouth and very extensively bound down to the lower jaw. The second patient, an Indian female of 55, had also had acute mercurial stomatitis, and this was followed by adhesion of the tongue along its entire left border to the left cheek. Both cases were relieved by operation.

A feature of the year was the publication of Dr. K. K. Chatterji's *Tropical Surgery and Pathology*, which was reviewed in our columns; and also in the *Tropical Diseases Bulletin* by Mr. J. J. Pratt. The latter reviewer remarks that such a textbook was badly wanted and that this volume will be most useful to house surgeons and to medical practitioners generally throughout the tropics.

Sub-assistant Surgeon P. B. Rau continues this year the melancholy story of tetanus in the *mofussil* with no antitetanic serum available, or the serum so expensive that neither dispensaries nor patients can afford it. In the absence of the antiserum, he advocates alternate subcutaneous injections of 20 minims of a 2 per cent. solution of carbolic acid, and of 20 minims of a 25 per cent. solution of magnesium sulphate; two injections of each being given during the first few days.

Dentistry is perhaps not surgery, but the plea in our issue for June by Mr. C. F. Badcock for the creation of a Dental Register, for a Dental Act for India, and for the establishment of an indigenous dental profession in India is one which, we feel certain, will evoke wide sympathy. Madras Presidency has led the way in this matter in India so far, but up to date nothing but the merely preliminary steps have been taken.

VENEREAL DISEASES.

The chief event of the year was the visit to India of the official deputation of the British Social Hygiene Council, consisting of Dr. David Lees and Mrs. Neville Rolfe. The lectures in Calcutta were very well attended and of very great interest. The venereal disease problem is probably considerably worse in the big cities of India, where only the mere fringe of the subject has so far been touched, than in the big cities of Great Britain where full and well organised facilities for modern diagnosis and treatment exist. Syphilis is rampant in this country, the general incidence of a positive Wassermann reaction is about 15 per cent., and the particularly severe effects of syphilis as a complicating factor in such tropical diseases as malaria, kala-azar, and leprosy make the position a specially difficult one in India. Something will have to be done about it sooner or later, we suppose; but, as with everything else, it is all a question of funds, men, and organisation. We doubt whether as many as one per cent. of cases of syphilis in this country ever receive adequate treatment, though it is probably true to say that the terrible tertiary cases which used to be seen so frequently in India in the pre-salvarsan days are now not encountered.

Very few papers call for remark. Major P. Power, R.A.M.C., has an extremely useful article, which was abstracted in our columns, on the toxic effects of the arsenobenzol compounds, with instructions as to how to avoid them and to treat them when they occur (*Journ. Roy. Army Med. Corps*, Jan., p. 46). S. R. Naidu claims that potassium silver iodide is of special value in the treatment of gonorrhœa. The salt is prepared by mixing one part by weight of crystallised potassium silver iodide and four parts of potassium iodide in strengths of 0.5 grm., 1.0 grm., and 1.5 grm. (we presume of the potassium silver iodide) in 20 c.c. of sterile distilled water. For acute cases the anterior urethra is first washed out twice with 10 c.c. injections of the weakest strength; then 20 c.c. of the same strength is injected and the glans bandaged so that the fluid is retained. In chronic cases 20 c.c. is slowly injected so as to fill the posterior urethra, the glans firmly bandaged, and the injection retained for from 15 to 20 minutes. If stricture is present dilatation is necessary before the injections can give good results. It is claimed that the method is painless and efficient; some six or seven injections leading to the disappearance of gonococci, even in the exudate obtained after prostatic massage.

Yaws continues to be a subject of discussion, and Dr. G. C. Ramsay discusses the introduction of yaws into Assam. He claims that all the evidence available, historical, geographical, and racial, points to an importation from Burma via the hill tribes of Assam. The *chako* of the Manipuris, the *saighree* of the Kukis, and the *chakaura* of the Nagas are all yaws, and are the equivalents of the *purru* of Malaya and the *kwe-na-bow* of Burma. The recent discovery (so far unpublished) during the year by Dr. E. Muir of a focus of yaws in the Singhbhum District on the Bengal-Bihar borderline is of interest in showing that yaws may have spread even further, and have invaded Bengal. A group of cases was encountered, the patients sent to the Calcutta School of Tropical Medicine for examination, and *Treponema pertenue* found. Clinically, these cases were typical of yaws, and not of syphilis; whilst they had been previously mistakenly diagnosed as leprosy.

HYGIENE AND PUBLIC HEALTH.

International.

Col. J. D. Graham, C.I.E., Public Health Commissioner with the Government of India, very kindly contributes the following review of the year.

In the past two issues of *The Indian Medical Year*, I have given a résumé of the progress of international health work in so far as it affects this country. In the following note, I shall endeavour to bring this information up to date for the year 1927.

The scope of the Eastern Epidemiological Bureau of the League of Nations at Singapore has steadily progressed and its utility is more and more recognised by the public health, especially maritime, services of the East. It continues to issue by wireless from Saigon and Bandoeng a weekly summary in code of the prevalence of infectious diseases at ports and information regarding the movements of infected ships; this message is picked up in India by Jutogh and is then disseminated at once by the Public Health Commissioner to all major ports and a few others in India. At present 137 ports of Asia, Australasia and the East Coast of Africa are sending weekly information to the Bureau, all of which is incorporated in the broadcast message sent out from Singapore.

This summary is re-broadcast by five wireless stations in the East and by the Nauen station in Germany.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A résumé of the message is also broadcast in clear by Bandoeng (Java), Tokyo, Madras and Karachi so that the information may be picked up by ships at sea throughout the East. The extended use of wireless broadcasting has very greatly diminished the expenses of the Bureau and bids fair to allow of a continuation of the Bureau's work once the Rockefeller subsidy has been withdrawn.

The Bureau further issues by post a weekly statement (fasciculus) giving information *in extenso* regarding the distribution of infectious disease and other matters important to the maritime public health services within its radius of activity.

As the representative of India, I presided over the meeting of the Advisory Council of the Bureau at Singapore in January 1927, and again at the meeting in Delhi in December 1927. In addition to framing the budgets of the Bureau, the Committee has dealt with the regularisation of the position of this regional Bureau *vis-à-vis* the parent Health Committee of the League, in view of its accepted permanent character. These meetings of representatives from Australia, China, Federated Malay States, Indo-China, Japan, Netherland, East Indies, Siam, Straits Settlements and the Philippine Islands result in extremely useful suggestions and discussions for increasing the Bureau's utility.

The Council further investigated the possibilities of co-ordinating research work in the East. It realises that the development of this activity must be slower than in Europe. At the meeting in January 1927, the international co-ordination of work on oral vaccination and research on plague was discussed and in connection with the latter an expert plague committee was nominated. This committee held a joint meeting with the Far Eastern Association of Tropical Medicine Congress in December 1927, from which resulted a resolution of the Congress and later one by the Advisory Council Eastern Bureau detailing in order of priority the investigations that are urgently required in connection with plague. The resolution of the Advisory Council is being communicated to the League of Nations Health Organisation at Geneva for communication (if approved) to the administrations which it affects.

As representative of the Government of India, I attended the Session of the Office International d'Hygiene Publique at Paris in April-May 1927. At this meeting, I again took the opportunity of presenting personally notes by Indian workers on their researches, particularly on such work as had an epidemiological bearing, with which aspect the Office is chiefly concerned. The subjects of the notes included McCarrison's work on the experimental production of beri-beri, stone-in-the-bladder and a new type of goitre; the forecasting of plague epidemics (Forster); the efforts at the Haffkine Institute to increase the efficacy of anti-plague vaccine; the work on the transmission of kala-azar by the Kala-azar Commission and by the School of Tropical Medicine, Calcutta, and on plague by Goyle. Special interest was evoked by the communications on cholera research and bilivaccine experimentation by Russell, Tomb, Brahmachari and Saranjam Khan. The importance of these notes was considered to be too great for casual discussion, and their consideration was deferred to a later meeting for preliminary careful study by the delegates.

At this meeting, an agreement was reached with the League of Nations regarding the rôle of the Singapore Bureau in the transmission of information required for the Paris Office in accordance with the Sanitary Convention of 1926. Similar agreements were foreshadowed as regards the Pan-American and the Melbourne (Australasian) bureaux. An interesting proposal was also brought forward for the establishment of a Middle East Bureau under the aegis of the Egyptian Sanitary Maritime and Quarantine Board for the distribution of epidemiological intelligence in connection with the Hedjaz pilgrimage and other cognate matters concerning the countries in the Middle East.

Another international meeting which affected India was the International Rabies Conference held in Paris in April 1927, at which Lieut.-Col. J. Taylor, D.S.O., I.M.S., represented the Government of India. The Public Health Commissioner was also able to arrange for the delegation of Lieut.-Col. McKendrick, I.M.S. (retired), a former Director of the Kasauli Institute, who was chosen to preside over the Section dealing with treatment. Delegates from 26 countries attended the Conference. The most important subject of discussion was the best method of treatment from the point of view of eliminating paralytic and other accidents. Opinions from India, where greater numbers are treated than in any other country, carried great weight—in fact, India's experience practically dominated the Conference.

The Conference did not finally make a definite declaration as to the best method of treatment, but it provided for further experimental work by comparative tests on a large scale. Such work is at present being carried out at the Pasteur Institute, Kasauli, and has already advanced matters considerably.

The outstanding international event of the year for India was the meeting of the Far Eastern Association of Tropical Medicine Congress at Calcutta in December, followed by tours of delegates throughout India. This gathering of experts in tropical medicine from all parts of the world has given India's problems and her attempts to solve them a publicity that cannot but have a useful effect on our own people and workers, and will also facilitate our international health relations with the administrations whose delegates have studied our conditions at first hand.

In my last year's review, I mentioned that the League of Nations had organised their first interchange of health officers in the East, modelled on those which had taken place in Europe and America. The 1926 interchange was held in Japan. In 1927, the Government of India extended an invitation to the League to hold their second eastern interchange in India. The offer was accepted and an extensive tour comprising Delhi Province, Punjab, United Provinces, Bihar and Orissa, Bengal, Madras, Bombay and the Indian State of Mysore has been arranged to take place in the first seven weeks of 1928. Sixteen officials are attending from Australia, Netherland East Indies, New Zealand, Philippine Islands, Siam, Straits Settlements, Japan, Ceylon, Federated Malay States, Indo-China, China and Egypt. The tour will give the visitors an intimate insight into all branches of health activity in India.

The International Sanitary Convention of 1926 has not yet been ratified by the Government of India and further delays have occurred in carrying out the legislative changes affecting our major ports that will be necessary before India is in a position to fulfil her obligations under the Convention.

The Indian Research Fund Association, with its financial status restored, has been able to finance a large number of important enquiries with a practical bearing on the preventable diseases from which India suffers. The progress of these enquiries is familiar to all readers of the *Indian Journal of Medical Research* and the *Indian Medical Gazette* and need not be described here. An expert Research Committee, under the Chairmanship of Sir Walter Fletcher, K.B.E., Secretary, Medical Research Council, meets in India early in 1928, and their report on the proposed Imperial Research Institute for India and on the general policy of the future Research Department will be awaited with interest.

Enough has been said in the foregoing short note to show that internationalism in health matters is a firmly established and a steadily growing activity, with which India must indubitably continue to concern herself.

The appointment of the Simon Commission to investigate the working of the Government of India Act of 1919 has necessitated our taking stock of the various phases of public health development throughout the different provinces of India during the period since the institution of the Reforms. In this connection, a comprehensive survey is being undertaken for the information of the Commission.

GENERAL.

Lieut.-Col. A. D. Stewart, Professor of Hygiene, Calcutta School of Tropical Medicine, kindly contributes the following general review.

If we were asked "What is the greatest obstacle to sanitary and medical progress amongst the masses in India?" the answer might be "Belief in a glorious past and in a blessed hereafter, and an indifference to the present." The real wonders and possibilities of human life on this earth are not yet realised by the masses in India; human life is held too cheap, produced too thoughtlessly and lost too lightly. Custom, prejudice, and sacerdotal authority still bind the great majority. The position is not without its parallel in history, and those of us who are interested in the physical regeneration of Indian peoples look for a sign of that leavening with which the whole will be quickened. Will the storm of indignation that the publication of a certain book aroused this year stir the people to a sense of regard and respect for Nature's physical processes?

In a notable debate in the Legislative Assembly on the Age of Marriage Bill, one member asserted that but for the British Government, those things would be done by Indians themselves. We wonder; but the freer discussions and expressions of opinions on child marriage, age of consent, widow remarriages, untouchability, etc., are hopeful signs that certain customs and views which, whatever their value in bygone times, are now undoubtedly impediments to healthful progress, are now beginning to be doubted and appraised as to their real value, apart from authority, tradition, custom and sentiment.

The year has not been particularly fruitful in sanitary legislation. The relation of the Reforms Act to health and sanitary conditions of India will be considered at the proper time by those specially appointed to do so, but we have a feeling that the advantages and opportunities given by the Act to provincial legislative councils have not been adequately utilised for constructive public health legislation, and that the responsibilities of freedom from central control in this respect have perhaps not been realised. In general administration the most notable advance has been the inauguration in Bengal of a rural public health organisation, based on the "thana" or police registration district. The Government of Bengal have agreed to the expenditure necessary to provide for each thana one assistant health officer, a sanitary helper and two menials. Already 100 such staffs have been trained and installed and another two years will probably see the completion of this network of preventive assistance. These staffs are under the District Board but will be inspected by the Public Health Department staff. Everyone agrees that a health staff in every province is a necessity, but there is at present no unanimity as to what form this staff should take as regards personnel and under whom it should work.

The Cantonment Act of 1924 was designed to give a more representative control over Cantonment affairs. As regards health, however, the new Act does not seem to have been precise enough in its definition of the Cantonment Health Officer, his duties and his relations to the Civil and Military authorities.

Most of the railways are now government institutions and the formation of Railway Medical Services, co-ordinated in staff, aims, and methods, should be one of the advantages of the formation of State Railways.

The health of school children and college students has attracted considerable attention. Major Webb in Simla has shown how successful a well designed scheme can be in Indian schools. The Calcutta University recommended compulsory physical training in all schools and colleges and also compulsory military training for all college students, and the former suggestion has been accepted by the government as a working principle.

The visit of the Social Hygiene Council to India stimulated interest in the treatment and prevention of venereal diseases work, though lack of funds would appear to be a likely deterrent to any active result of the visit.

Food and nutrition have received a considerable amount of attention. Col. McCarrison's work at Coonoor and his evidence before the Agriculture Commission have convinced most of the close relationship of diet to national physique and national character, and in both the central and provincial legislatures the subject of diet, foods, and foodstuffs has been intelligently and keenly discussed. The importation of large quantities of hydrogenated oils, probably all vegetable in origin, resembling *ghee* in appearance and taste, may not be without significance; for these are entirely lacking in vitamines A and D and the consumption of such oils in place of *ghee* over extensive areas may have far reaching and serious effects on the growth and physical condition of the coming generation. Major Hughes, Chemical Examiner with the Government of the Punjab, conducted some experiments which show that the fat soluble vitamines are entirely lacking in these oils. The problem is on a par with that of "butter *versus* margarine" in England and the same rules should apply. The sale of such fats cannot be forbidden; they are cheap sources of fats and energy, but the public should not be defrauded into thinking they are getting the more valuable food, and there should be no possibility of any such masquerading, or adulteration of *ghee* with these oils. The Madras Corporation have now adopted regulations and standards for the main foods. The Calcutta Corporation have also been provided with standards of purity under the 1923 Act. Bombay, so far as we know, is still behind hand. The Food Adulteration Act has now been applied to rural areas of Bengal, a very notable advance.

Important work has been carried on in the standardisation of *ghee* and other fats and oils in the Calcutta School of Tropical Medicine, and Dr. Brahmachari's paper on *ghee* standards was a valuable contribution to this question.

Water Supplies.—Calcutta is extending its supply of filtered water to give 57 gallons per head per day. The danger of putting new wine into old bottles has been illustrated by the serious contamination of the filtered water in some parts of Calcutta owing to old defective pipes laid in old sewers, and to the intermittent supply. Some people are concerned, however, about the Corporation bringing so much more water into the city without any adequate provision for taking it out, for most of it must go out again. The disposal of Calcutta sewage and its excess drainage is still a knotty problem. The Corporation have rejected the invitation to form a committee preliminary to a Main Drainage Board to deal with the riparian drainage. Experiments with activated sludge have shown that the Calcutta sewage, after 4 hours' aeration with a good activated sludge, would give a very good, stable and inoffensive effluent.

Bombay is chlorinating its main Tansa supply. Madras is still having trouble with its filters with the production of hydrogen sulphide and would appear to be shy of taking a bold step in purification. Cunningham in Madras and Taylor in Rangoon have contributed to our experience of the methyl red and the citrate tests for the coliform organisms found in water. This work is very interesting, but from a practical point of view does not take us much farther than Clemesha's original classification, with which these newer tests would seem to be in agreement.

Sewage Disposal.—The question of the disposal of sewage and storm water in Calcutta and Bombay are still in the same stage. The formation of a Main Drainage Board to study the drainage problems in and around Calcutta has received a check by the refusal of the Calcutta Corporation to appoint their engineers on a preliminary committee. This is a pity as most are agreed that such a Board would be of great assistance in improving the drainage conditions on both sides of the Hooghly, a very difficult and complicated problem. On the experience of Dacca, treatment on land has been applied to several new schemes in Bengal, at Tittaghar and elsewhere. Work on the activated sludge process has been carried on in Bangalore, Jamshedpur and at the Calcutta School of Tropical Medicine.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Owing to the climate, the sludge difficulty in India is not so great as in Europe and the process would seem to offer very material advantages, especially for the treatment of septic tank effluent, the treatment and disposal of which has never been really practically satisfactory.

Cholera.—The work done by Russell in Madras is a valuable contribution to our knowledge of the epidemiology of cholera. Rogers' paper drew attention to the question of cholera as a whole in India. He is probably right in stating that there are several endemic areas in India in addition to Bengal, but Russell has questioned his conclusions as to the relationship of humidity. Mass inoculation for cholera is making headway, especially in Bengal, and Russell's assurance that the belief in the efficiency of this measure is based on sound argument has helped immensely in pushing propaganda measures. Bilivaccine would appear to be inferior to hypodermic injections as a protection. Brahmachari in Bengal has worked on the serological relationship of the non-agglutinating type of vibrio found in healthy people in endemic areas. In agreement with Tomb and Maitra he considers that the non-agglutinating vibrio has a close relationship to the agglutinating vibrio and is closely concerned in the production of cholera epidemics. More work and experience on this point is needed. d'Herelle's work on the bacteriophage of cholera carried out in India in 1927, if substantiated, is likely to be of great importance in dealing with the problem of endemic and epidemic cholera.

MADRAS.

Lieut.-Col. A. J. H. Russell, C.B.E., Director of Public Health, Madras, reviews the year in Madras as follows:—

During the year 1927, Government sanctioned the appointment of 1st class Municipal Health Officers for the Municipalities of Masulipatam and Cuddalore and of 2nd class health officers for 6 additional Municipalities. One additional District Health Officer and 4 Health Inspectors were also sanctioned for the new district of West Godaveri. At the end of 1927, 25 District Health Officers and 34 Municipal Health Officers were in employment. 47 of the 81 Municipal towns in the Presidency still have no Health Officer.

Prior to 1927, spasmodic efforts had been made from time to time by the Public Health Department for the better control and the prevention of malaria in the Presidency. The investigation units attached to the King Institute have been in constant demand during the last three years, but malaria was only one of a dozen diseases with which they were asked to deal. In order that systematic steps might be taken to deal with the problems associated with malaria, proposals were made in 1925 and 1926 for the appointment of a malariologist who would investigate malarial conditions in selected areas and advise the Government and local bodies as to the measures to be taken to reduce the disease from the areas investigated. The Government sanctioned, with effect from 1st April, 1927, a temporary malaria officer on Rs. 900—50—1,500, with an assistant, two laboratory attendants, and establishment. The Special Malaria Officer works under the direction and control of the Director of Public Health. Investigations have been commenced and have already been completed in four areas.

The experience gained by the Madras Health Council during the last four years of its existence has given valuable information as to the nature of the propaganda materials, e.g., posters, leaflets, etc., which are most appreciated by the people. Its work, however, was only made possible by donations from the Indian Red Cross Society and by grants from Government, whilst, during 1926, various contributions from local bodies were received. The demands for the Council's materials continued to increase so rapidly that, with the restricted funds at its disposal, it was found impossible to meet these. Moreover, practically the whole of the work fell on officers of the Public Health Department. The suggestion was therefore made that a propaganda section should be created in the office of the Director of Public Health to carry on the work of the Madras Health Council. The Madras Health Council agreed to dissolve and hand over their whole stock of lanterns and literature to the new section. The proposals were sanctioned by Government and with effect from 1st April, 1927, an officer with the necessary qualifications and with the necessary staff to assist him has been appointed. A small non-official auxiliary committee has also been formed to keep the department in touch with non-official bodies and societies whose activities include health propaganda work.

In order to organise and assist in the carrying out of anti-hookworm measures in the rubber and tea estates in the Presidency, Government sanctioned with effect from 1st April, 1927, for a period of two years the appointment of a 1st class Health Officer to work under the Director, Ankylostomiasis Campaign. An officer with the necessary qualifications has been posted and is carrying on his work with headquarters at Ootacamund with considerable success.

Vaccination and Small-pox.—Figures of mortality from small-pox during the last 5 years are given below:—

1923–24	22,626
1924–25	20,227
1925–26	14,498
1926–27	9,816
1927–28 (7 months)	4,567

Nearly two million people were vaccinated during the year 1926–27 with a success rate of 95 per cent. as against a rate of 94.7 per cent., 94.6 per cent. and 90 per cent. during the years 1925–26, 1924–25, and 1923–24 respectively. The lymph in use may be said to have the highest possible protective value.

During the year the Public Health Code (Vaccination) was revised and the new edition has been issued.

Some trouble with anti-vaccinationists arose in Tanjore and Chittoor districts during the year and propaganda work was done by the health staff to counteract their activities.

As the quality of vaccination work done by unqualified vaccinators in certain local boards and municipalities was not up to the mark, all presidents of Local Boards and chairmen, Municipal Councils, were asked to replace unqualified candidates by qualified men. Such of the local bodies as refused to do so were surcharged.

The vaccinators' equipment was also revised during the year.

National Health and Baby Week.—The National Health and Baby Week has become an annual function, and the 4th week in the Presidency was celebrated during the months of February and March 1927. As in 1926, widespread infection with cholera prevented the celebration in the district of Tanjore and in certain other rural areas and municipalities.

The week was observed in 7,007 centres, 28,485 lectures, including magic lantern lectures, being delivered on health subjects. In addition 67 cinema shows were given as against 9 in 1926 and exhibitions organised in 787 centres against 298 in the previous year. No less than 2,120 baby shows were held. A sum of Rs. 1,37,327 was collected and spent during the week.

Taken as a whole, the Health Week of 1927 was carried out more extensively and more successfully than in previous years. The District Challenge Cup was won by the Salem district, the Municipal Shield by the Cocanada municipality and the Union Challenge Cup by the Penukonda Union Board.

Public Health Act.—Government have dropped the proposal to frame a consolidated Public Health Act for the Presidency. The question of amending suitably the existing Local Board and Municipalities Acts is being considered and it is hoped that amending bills to these Acts will shortly come up for discussion in the Legislative Council.

Vital Statistics.—The estimated birth-rate is about 36.0 per mille, practically the same as in 1926. The death-rate from all causes is 23.8, the rate for 1926 being 25.6 per mille. The mortality from epidemic

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

diseases was less than in the previous year except in the case of cholera.

This disease prevailed in a virulent form especially in two districts. In one of these districts (Nellore) the disease broke out shortly after the district was devastated by a cyclone in November.

A geographical survey of plague on similar lines was also completed. The history of the present visitation of plague from its first appearance in the Presidency in 1898 has been written. The endemic and epidemic foci of the disease were mapped out and its seasonal behaviour was investigated.

Malaria.—The Government of Madras have been pleased to accept proposals made last year for the appointment of a Special Malaria Officer to work under the Director of Public Health. As was pointed out in the notes for 1926, the appointment is only a resuscitation of work sanctioned as long ago as 1912 but interrupted on account of the war. The Government have further desired that the investigation into malaria and its problems should be carried out in the first instance in selected municipal towns and other areas known to be badly affected with the disease and that definite proposals for its total eradication or prevention which will be of a practical nature should be submitted to them so that they can take necessary steps in co-ordination with the local authorities. The appointment is made on a temporary basis for a period of two years; but it is hoped that in course of time as the work progresses, the Government will realise the need for permanent malaria organisation in this Presidency.

If this is done, they will only be falling into line with the active steps now being taken in other parts of India. In this Presidency vast tracts of rural country exist in which the ravages of malaria have restricted both social and economic advance.

The Special Malaria Officer commenced work early in July 1927, after having been deputed to Kasauli for a couple of months. He is assisted by an assistant surgeon who has undergone a course of training in malariology at Saharanpur. Malaria investigations in three municipal towns, namely, Bellary, Vizagapatam and Hospet, in the rural Union Town of Vriddhachalam and in the mining area in Sandur state in Bellary District have already been completed. These places may be taken as representing typical affected areas. Bellary is a town situated at about 1,400 ft. above sea level. It is the headquarters of the district called by the same name which forms the northern boundary of the Mysore plateau. This tract of country is largely hilly. Bellary town is both a civil and cantonment station, although its importance as a military station is now insignificant. Malaria here is intimately associated with the large number of rock pools and obstructed drainage channels on the top of the Fort hill separating the civil town from the cantonment, and with a feeder channel which runs along the irregular rocky bed to a large tank within municipal limits.

Hospet is another municipal town in the same district. There the problem of malaria is associated with numerous irrigation channels and wet cultivation lying in and near the northern parts of the town.

Vizagapatam is a sea-port town now coming into prominence on account of the new harbour which is in the course of making. The town is hemmed in between the sea and ranges of low hills. The offending water-places here are the hill streams which meander through the town towards the sea.

In Vriddhachalam, with its warm moist climate, the danger zone is constituted by pools along the course of a number of surface springs situated to the north of the town and running towards a river and by innumerable pools in the river bed itself which surrounds the town on the north and east.

The mining area in Sandur state affords a typical example of hill malaria.

In addition to making the routine malaria surveys of selected areas as stated already, it is proposed to carry out observations both in respect of the seasonal and other variations of anopheline fauna and the progress of anti-malaria works and their effects in the areas dealt with. It is also hoped to make a detailed study of the bionomics of anopheline mosquitoes in the Presidency.

Epidemiology of Cholera.—Statistical studies in the epidemiology of cholera have resulted in many interesting and useful discoveries.

In the first place the short and simple method of computing and reducing correlation coefficients(1) has made extensive statistical work in India a working possibility. Only those who have actually used this short method can realise its possibilities in correlation work.

The question of forecasting epidemics of cholera(2) has been answered by the application of methods enunciated by Bundesen and Hedrick. By means of this method a standard is established with which present mortality figures can be compared with those of previous months or years, the median being chosen as the average over the period of years considered. By this method it is possible to forecast epidemics of cholera well in advance of the actual occurrence and to keep a constant watch for the advent of epidemics. It is, therefore, necessary to organise preventive measures only in times of epidemics and money and effort in unnecessary directions at other times can be avoided.

This method may also be applied to other epidemiological data in India for the same purpose.

During the present year, the rôle of the climatic factors: rainfall, relative humidity, temperature and pressure in the occurrence and spread of cholera was further analysed. The results have been set out in full detail in "Epidemiology of Cholera (V)," which will shortly appear as a memoir in the *Indian Journal of Medical Research*. This memoir attempts to interpret the network of simple and partial coefficients of correlation of all orders with special reference to the endemicity and epidemicity of the areas considered. The conclusions may thus be summarised.

(*a*) Rainfall has no direct effect on the incidence of cholera, but merely assists temporarily in the distribution of infection.

(*b*) Relative humidity has a decided effect on the incidence and spread of cholera, but is dependent on temperature conditions.

(*c*) Temperature has effect only in certain areas and is dependent on humidity conditions of the atmosphere.

(*d*) Pressure has no effect except in the sense that all the climatic factors may be said to have some general effect.

(*e*) In general an atmosphere in which high relative humidity coincides with high temperature, accompanied by intermittent rains, is especially suitable for the spread of cholera epidemics.

(*f*) Some provinces of India are endemic, like Assam. Bengal, the Southern Districts of Madras Presidency and the banks of the great rivers, viz., the Ganges, the Brahmaputra and the Kavari. The epidemic indices,(3) the monthly mean and median deaths and the zero order and partial correlation coefficients for each area have all corroborated this classification.

(*g*) Outbreaks of cholera are primarily due to the existence of carriers, but suitable atmospheric conditions and fairs and religious festivals help in spreading the disease.

In this brief survey, it is impossible to present in any suitable abbreviated form, the large number of correlation coefficients which were computed and taken into consideration. As far as cholera epidemics are concerned it is of little advantage to try to locate the part played

Digitized by Arya Samaj Foundation Chennai and eGangotri

by any one climatic factor when the others are held constant.

Rainfall has clearly no effect. The other climatic factors are active rather than passive, and are of importance in determining the virulence of epidemics. In epidemic areas, the combination of high relative humidity with high temperature, accompanied by intermittent rainfall, constitutes a favourable atmosphere for the spread of cholera. In endemic areas, however, such a combination is not necessary either for its development or spread.

The provision of pure water-supplies, rapid collection and disposal of refuse and night-soil, the extension of health organisations and staffs, the immediate notification of outbreaks of the disease, are all important essentials which should receive more and more attention. The control of cholera by means of prophylactic inoculation has been tried in certain areas in Tanjore District. Analysis of the inoculation data has shown in somewhat conclusive fashion that protection against cholera is conferred by both the anti-cholera vaccine and by bili-vaccine, but that the former is more effective than the oral vaccine. Experience, however, has shown that it is entirely impracticable to undertake mass inoculation of the pilgrim populations even at the more important festival centres.

The bearing of the population problem(4) on the occurrence of epidemics is indicated by the well known principles of Malthus.

The only way in which control of cholera is possible in India lies in the co-operation of all concerned in the preservation of pure water-supplies, in the spread of knowledge of the rules of hygienic living. Only then will it is possible to hope for the control and eradication of this deadly enemy of mankind.

Relapsing Fever.—Cases of relapsing fever were reported during the year from Dharapuram Taluq of Coimbatore district and the Periyakulam Taluq of Madura district. A few cases were also reported from some of the tea estates in the Nilgiris district. These were mostly imported from Madura district. A campaign against relapsing fever has been started in Madura district and a sum of Rs. 2,000 has been sanctioned by the District Board for the purpose. The disease continues to be entirely confined to the poorest classes. The case mortality has been small and the spread of infection has been fairly well controlled, although the insidious nature of the infection and belated information of outbreaks have added to the difficulties.

Food Adulteration Act.—In his report on food standards under the Madras Prevention of the Adulteration Act, 1918, the Public Analyst pointed out that the Act was defective in certain respects and suggested certain amendments to the 1918 Act. An amending bill was presented to the Legislative Council and was passed into law in October.

UNITED PROVINCES.

Lieut.-Col. C. L. Dunn, D.P.H., I.M.S., Director of Public Health, U. P., reviews the year as follows:—

The year has been an exceedingly successful one for the Public Health Department of these provinces and there has been great expansion in the activities of the department in every branch.

Superintending Agency.—The Superintending Agency now consists of a Director of Public Health and six Assistant Directors. Until this year, four Assistant Directors were employed on routine duties in the four ranges into which the province was sub-divided, but this year a re-arrangement has been made and the province is now divided into three ranges, it being found that owing to the expansion of the district health service, three inspecting officers were sufficient to cope with the routine duties of the department. A new appointment to take the place of one of the abolished ranges has been made by putting an Assistant Director in whole time charge of the Hygiene Publicity Bureau, the activities of which branch have greatly expanded. The 5th and 6th Assistant Directors are in charge of the Provincial Hygiene Institute and the Malaria Branch respectively.

Provincial Public Health Service.—The Provincial Public Health service now consists of two classes.

Class I, officers possessing a Diploma of Public Health of the Lucknow University or an equivalent or higher qualification. Class II, officers possessing a License in Public Health of the U. P. State Medical Faculty or an equivalent or higher qualification. Officers of Class I fill the appointments of District Medical Officers of Health in districts and Municipal Medical Officers of Health in the first and second class municipalities. Officers of Class II fill the appointments of Assistant Medical Officers of Health in districts and Medical Officers of Health of Class III municipalities. The numbers of Class I Municipal Medical Officers of Health have expanded to 20 out of 21 sanctioned appointments. The numbers of Class II Medical Officers of Health have expanded to four out of ten sanctioned appointments. The vacant appointments are being filled as rapidly as fully qualified personnel becomes available.

The numbers of District Medical Officers of Health have expanded to 26 while the numbers of Assistant Medical Officers of Health are now 27. Thus more than half the province has been provided with a district health service and it is expected that the whole province will be staffed with fully qualified officers within two years, the only delay in expansion being the paucity of qualified officers.

These officers are now wholly paid by Government instead of being paid partly by the local bodies and they, therefore, have acquired the necessary security of tenure to make the service attractive and popular. Until this year these officers were appointed and dismissed by the local bodies, often for reasons quite unconnected with their professional abilities. This I consider one of the greatest advances that has been made in the Department for many years. The service of municipal sanitary inspectors still remains a local service, but appointments can only be made of qualified men from the approved list maintained in the office of the Director of Public Health and on salaries and conditions of service laid down by Government. The number of sanctioned appointments at present is one to 20,000 of the municipal population. The service of district sanitary inspectors is also local and now consists of 106 sanitary inspectors in 26 districts.

Provincial Hygiene Institute.—The new building for the Provincial Hygiene Institute which was sanctioned in 1926, is now nearing completion and provides accommodation for training 20 candidates for the Diploma of Public Health of the Lucknow University, 20 candidates for the License in Public Health of the State Medical Faculty, 60 candidates for the Apprentice Sanitary Inspectors, and 40 candidates for the sanitary inspectors certificates in each case of the U. P. Government. At present the institute is carrying on its training work of the future public health personnel of the province in restricted quarters provided by the King George's Medical College, and owing to lack of accommodation a far smaller number can be trained than is necessary for the needs of the province. The institute will also be equipped with chemical and bacteriological research laboratories.

Hygiene Publicity Bureau.—As stated above, the Hygiene Publicity Bureau is now the wholetime charge of an Assistant Director of Public Health, and excellent work is being carried out by the Assistant Director with the help of staff of one Medical Officer of Health of the first class and one of the second class.

Malariology Branch.—The Malaria Branch which consists of an Assistant Director and two first class Medical Officers of Health has carried out excellent work during the year, especially in connection with the construction of the Sarda Canal. The Assistant Director of Public Health (Malariology) is in addition Chief

(4) "Population and Public Health." By Lieut.-Col. A. J. H. Russell, C.B.E., I.M.S. Read before the Congress of the Far Eastern Association of Tropical Medicine, 1927.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Medical Officer of the Canal, a convenient arrangement which has enabled him to control malaria among the large number of labourers employed to such an extent that in the opinion of the Chief Engineer, without his work the canal would have taken at least two years longer to build. At the headworks, which are situated in one of the most malarious tracts in India, viz., the sub-Himalayan terai, many permanent and temporary anti-malarial works have been carried out.

The anti-malarial classes for Medical Officers of Health lasting one month were held as usual and the numbers of officers attending were 10. During the year a complete anti-malarial survey of the remaining Tehsils of the Bhabar and Terai Government Estates was completed and on the recommendations of Capt. Clyde and his immediate predecessor, Lieut.-Col. J. A. S. Phillips, I.M.S., large sums of money are being spent by Government in rendering settlements in this tract non-malarious and in moving settlements from highly malarious areas to other areas more suitable for colonization. In addition, malarial surveys of several towns and rural areas have been completed.

Hardwar "Kumbh" Fair.—During the year the great "Kumbh" fair at Hardwar took place in March and April and the biggest gathering of pilgrims ever recorded are estimated to have attended the fair, the number on the 13th April being over 9,00,000. Complete and comprehensive arrangements for the prevention of epidemic disease had been organised for some considerable time beforehand with the result that every case of cholera imported into the fair was rapidly isolated and all contacts segregated with the result that only 58 cases of cholera occurred. These are treated in a fully equipped Infectious Diseases Hospital which has recently been completed and which contained an up-to-date bacteriological laboratory with the result that 32 recovered and 26 died. The chief problem in connection with huge pilgrimages of this description is to rapidly isolate the cases so as to prevent the spread of infection. Many were caught at the railway stations *en route* to Hardwar and others while dispersing from the fair.

Food and Drugs Act.—Great advances were made in the organisation of detecting the adulteration of food and drugs as compared with previous years. The Public Analyst examined 790 samples during the year up to date, as compared with 933 in the previous year, and 284 against 317 were found to be adulterated. The Act has been extended to many towns and to certain rural areas.

Vaccination.—The Bovine Lymph Depôt at Patwa Dangar issued 252,043 grammes of calf lymph during 1926-27 and 1,433,056 persons were vaccinated as compared with 216,107 grammes and 1,465,862 persons, respectively, in the previous year. The percentage of successful results in primary vaccination in 1926-27 was 94.79.

BURMA.

Lieut.-Col. G. G. Jolly, C.I.E., M.B., D.P.H., D.T.M. & H., I.M.S., Director of Public Health, Burma, reviews the year as follows:—

Malaria.—Surveys were carried out in Myitkyina, Mawlaik, Kyaukpyu and a village tract in the Yamethin District. Palliative measures in connection with trimming and oiling of Bhamo lake were also undertaken in October and November. Sanction has been received for the establishment of a Malaria Bureau in the Harcourt Butler Institute of Public Health under the charge of Assistant Surgeon Feegrade.

Kaws.—Surveys were carried out in the Mandalay and Lower Chindwin Districts, which have revealed widespread distribution of the disease in these localities.

Mak-Aw-Lam.—A Committee consisting of Col. Morrison, I.M.S., Major Smith, I.M.S., and Dr. U Tha Noo, was appointed by Government to investigate and report on *mak-aw-lam*, a supposed new disease in Burma, which has turned out to be mainly malaria. The Committee's report has been submitted to Government.

The Rangoon Health Enquiry Committee completed its work in February, 1927, and submitted a report to the Local Government.

Cholera.—There were 4,238 deaths against 6,182 in 1926. Nearly 90,000 doses of cholera vaccine were distributed.

Plague accounted for 3,454 deaths against 2,906 in 1926. Over 100,000 doses of vaccine were distributed as against 67,000 doses in 1926.

Small-pox was less severe, accounting for 1,274 deaths as against 2,399 in 1926. The Vaccination Acts were extended to the notified areas of Lashio, Kalaw, Loilem and Taunggyi in the Shan States and the Prohibition of Inoculation and Licensing of Vaccination Act was extended to the Myingyan District.

Vaccine Depôt, Meiktila.—Mr. G. H. Blaker, I.M.D., Director, Vaccine Depôt, Meiktila, was deputed to study the process of lymph manufacture at the King Institute of Preventive Medicine, Guindy, Madras, from 26th October to 17th November, 1927. Bacteriological examination and potency tests of the lymph have regularly been carried out at the Depôt Laboratory. The total number of doses of lymph issued during 1926–27 was 974,229.

Hygiene Institute.—The appointment of a whole-time Director for the Institute from the 1st March, 1928, has received the approval of the Finance Committee. Chemical and bacteriological analytical work in connection with public health is now being done at the Institute and the chemist to the Institute has been declared by the Local Government to be the Chemical Examiner for the purposes of the Burma Ghee Adulteration Act. Four sub-assistant surgeons of the Public Health Department are being trained at the Institute for the newly instituted Government License in Public Health.

Classes are also being held at the Institute for the normal students of the University College for their courses in School Hygiene. The Red Cross Society (Health Education Section) and the Infant Welfare Society hold their meetings at the Institute.

Scheme for full time health officers.—A scheme for the appointment of full time health officers in urban and rural areas on a half-pay grant system has been approved by the Local Government. A beginning is to be made in 1929 by appointing three 1st class and five 2nd class health officers. Full time health officers have already been appointed in Akyab, Prome and Pegu municipalities.

Health Officer for fairs and festivals.—A post of Health Officer to investigate sanitary conditions at fairs and festivals was sanctioned for a period of 17 months from the 1st October, 1927, and Dr. U Ba Kin, M.B., D.P.H., appointed.

Hygiene Publicity Bureau.—The appointment of the Hygiene Publicity Officer and his staff was made permanent from the 14th July, 1927. Two cinema films on "One Scar or Many" and "Public Health Twins at Work" were purchased for health propaganda work. A film entitled "The Village Well" dealing with a cholera outbreak in a village was prepared locally.

Public Health Engineering Department.—A proposal for creating a Public Health Engineering Department under the Ministry of Public Health is under consideration of the Local Government.

Food and Drugs Legislation.—A Food and Drugs Bill has been drafted and is under consideration by a Select Committee of the Legislative Council.

Venereal Diseases.—A delegation from the British Social Hygiene Council visited Burma during the year, and spent nearly a month in the country. Their report has recently been received by the Local Government.

A Bill for the better treatment and prevention of venereal disease is under consideration by the Local Government.

Leprosy.—Notifications extending the provisions of the Indian Lepers Act to the whole of Burma have been issued by the Local Government and the Local Government has sanctioned as an experimental measure for a period of two years the establishment of several dispensaries for the treatment of lepers in selected villages. Two private medical practitioners and three sub-assistant surgeons of the Medical Department were deputed by

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the Burma Leprosy Committee, to undergo special training in the treatment of leprosy in the Calcutta School of Tropical Medicine and Hygiene. A Leprosy Survey party of the British Empire Leprosy Relief Association arrived in Burma towards the close of the year to carry out a leprosy survey in the Chin Hills District. The Local Government has deputed four sub-assistant surgeons to work in co-operation with the party.

Miscellaneous.—Col. Bisset, Major Jolly, Dr. Crow and two assistant district health officers attended the Congress of the Far Eastern Association of Tropical Medicine held in Calcutta in December, 1927. Many foreign delegates to the Congress passed through Rangoon *en route* and were shown objects of medical and public health interest in Rangoon.

MISCELLANEOUS.

In our issue for October, we published a very important article by an anonymous contributor on the need for a well planned public health policy for India. We do not often publish anonymous contributions, but this article was written by a distinguished officer in the public health field, and the subject is most ably dealt with, whilst it is one of profound importance to India. The same issue also contained a covering editorial to the same article by Col. Megaw. Without desiring in any way to offer criticism, one may say that for many years the divorce between the Medical and Public Health Departments in the different Governments of India has retarded progress; whilst the fact that neither Surgeons General nor Directors of Public Health have the status of Secretaries to Government in their Departments places them in an inferior position where their recommendations perhaps carry less weight. Fortunately, with regard to the Imperial Government at least—and we think that we can say the same of the Provinces—the divorce between Medical and Public Health Departments is now at an end; for nothing could be more cordial than the relationships between the Public Health Commissioner with the Government of India and the Director-General, Indian Medical Service, and their offices, whilst the former officer is also Secretary to the Indian Research Fund Association. With medicine and public health transferred subjects, but medical research a reserved subject, the position is not an easy one, but any medical research worker of to-day in India who contrasts conditions as they now are with what they were in Sir Ronald Ross' day in India will recognise how deep a debt of gratitude he owes to the late Sir Pardey Lukis for his able re-organisation of the Medical Research Department in India. Conditions are now utterly different from what they were in Sir Ronald's day; there are the vast problems to be faced; there is financial provision for their investigation; equipment is not spared; the one cardinal difficulty appears to be to recruit men of the right type to investigate them. Here, again, we have to recognise the wise policy of Government in appointing the Fletcher Committee to go into the whole question and advise, though its report is bound to the subordinate to the report of the Simon Commission which will cover the far wider field.

In one particular matter perhaps there is a defect. The progress of medical discovery is almost continuous in this country, and if anything was wanted to encourage both Indian and European medical research workers in India, it has been provided in the enthusiastic comments on their work by our foreign visitors to the Far Eastern Association of Tropical Medicine Congress last December. But there does seem to be a hiatus between medical discovery and the application of results. To give a concrete instance, the mode of transmission of guinea worm infection is now well known and prophylactic measures are neither very expensive nor difficult of application. Yet guinea worm infection is still extremely prevalent in certain areas of India. We suppose that, as usual, it is a question of funds and personnel. India is certainly awake now to her malaria, kala-azar, leprosy, and tuberculosis problems; there has been an enormous amount of work on the prevention of hookworm infection, though roundworm infection is probably of more real importance in causing disease in this country. On a general review of the situation, whilst we cannot feel content with what has been done, yet very much *has* been done, and one cannot fail to realise this. Government is blamed continuously and in no measured terms by medical and lay newspapers, but the very stream of abuse is a measure of the success achieved. The "public health conscience" is the one great factor lacking, but it can be brought about by education, by inculcating hygiene in the schools. One of the most popular features in the life of India to-day is the cinema, and the potentialities of the cinema in educating the Indian populations in public health matters are almost immeasurable.

FOODSTUFFS.

A curious feature of the year has been the special attention paid to foodstuffs. A good example is the paper by Dr. B. B. Brahmachari and N. K. Chatterjee in our issue for July on the value of the "water nut" *Trapa bispinosa* as an article of diet. This is a water plant which is of great value as a supplementary staple food. As a food for invalids the fresh nuts are very suitable, whilst its flour compares favourably with such farniaceous foods as arrowroot, sago and rice. It has a high iron and phosphorous yield and may be of hæmatinic value, whilst it is very easily cultivated. A second paper dealing with foodstuffs is one by Mr. N. K. Roy on the quality of milk of some breeds of Himalayan cattle. He shows that the fat content in the milk from certain varieties of Darjeeling cattle is as high normally as 7.5 per cent., and deals with the factors which influence the quantity and quality of the milk yield. The Siri and Nepali cows are selected as being those which yield a very high fat content in the milk and are equal to English cattle in this respect, though inferior to them in the total yield of milk obtained.

Dr. B. B. Brahmachari deals with the constants of pure cow *ghi*. He claims that the butyrorefractometer reading is unreliable as a test for the purity of this article, but that the Reichert Wollny test is reliable. With the latter, if the reading is less than 19.5 c.c. the sample is certainly adulterated; if it is above 19.5 c.c. and its relation to the other two constants is upset, the sample is adulterated; and with Reichert Wollny values below 24 c.c. and *ghi* blended from products of a large number of cows, the chances of the sample being pure are negligible. Capt. D. R. Thomas deals with vegetable *ghi* (*vanaspati*), a Dutch preparation which is largely imported into India. He concludes that it cannot be used as a substitute for pure *ghi*, and cannot be given to infants and lactating mothers. It makes a good cooking oil, however, and is frequently used to adulterate genuine *ghi*. It is deficient in vitamines, but this deficiency could be made up by taking eggs or green vegetables such as spinach with it. As India cannot produce sufficient *ghi* for the requirements of her population, it is very desirable that these pure vegetables fats which appeal so much to the non meat eating races of India should be made more nutritious.

An interesting study of the production of soda water from the water of a deep tube well is given by Mr. N. L. Banerjee, M.SC. He concludes that for the manufacture of soda water from a tube well water having a high temporary hardness, the water should be softened with lime. The dose of lime added should be just sufficient to eliminate all the temporary hardness, excess or deficiency being inhibitory to the carbon-dioxide absorbing power of the water. The addition of soda-salt or sodium bicarbonate does not help to increase the absorbing power of the water.

Milk.—Lieut.-Col. C. Maddock, C.I.E., I.M.S. (retd.) deals in the *Lancet* with pasteurisation of milk. It is very doubtful whether pasteurisation is the ideal process. It diminishes the amount of diffusible calcium in the milk and reduces its value in the promotion of growth and weight in young children. Fruit and cod liver oil can be used to supplement this deficiency, but even with such additions pasteurised milk is not as growth

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

promoting as "certified" milk, "Grade A, tuberculin-tested" and obtained under strictly aseptic precautions. In India it is not so much the tuberculosis danger in milk that is important, as the prevention of gross contamination. It is clear that pasteurisation is not the ideal remedy for this, but we fear that "certified milk" is an almost unattainable ideal in this country.

WATER-SUPPLIES.

Rao Sahib V. Govinda Raju has investigated the bacterial efficiency of mechanical gravity filters. He concludes that systematic monthly examinations extending over a period of two years, and occasional hourly examinations during the period of a whole day's run, show that the *B. coli* content of the filtered water bears a direct relation to that of the feed water, and that ordinarily the number of *B. coli* that succeed in passing through the filters constitute about 10 per cent. of those present in the unfiltered water. Where chlorination is not practised the raw water should be stored sufficiently long for it to reduce its *B. coli* content to approximately one per c.c. These gravity filters show a higher bacterial efficiency during certain times of the year when algal growths are more prevalent.

The same author has also investigated the causes and prevention of corrosion of iron pipes and tanks. Corrosion is chiefly brought about by large metal surfaces being exposed to large amounts of dissolved carbon dioxide, and the latter can be removed by the addition of a suitable amount of lime. The insoluble carbonates which are thus produced must be removed by some form of sand filtration, and pressure filters seem to be better in this connection than gravity ones. Storage tanks require to be systematically painted so that their water never touches the metal surface; the strainer system should also be similarly painted, and special attention should be paid to the inner coating of pipes. The introduction of algæ into the overhead tanks in the hope of its leading to the formation of a slimy coating on the inside of the pipes appears to be worth trial. The stagnation of water in the pipes at night is a common cause of corrosion of pipes, and pipes should be completely emptied at night when water is not in use. The custom of emptying the overhead tanks at short intervals and thoroughly scraping them is actually harmful and not beneficial, as it destroys the naturally formed protective coatings of algal scum.

Lieut.-Col. J. Taylor, Major C. de C. Martin, Sub-Assistant Surgeon J. V. R. Naidu, and P. N. R. Naidu compare the results of Clemesha's method and the test of citrate utilization as applied to the water-supplies in Burma. They conclude that Clemesha's method appears to give results which approximate most nearly to the sanitary circumstances of the water samples tested. The presence of citrate non-utilisers only or in large proportion in a water sample is not sufficient evidence of pollution. The combined use of the citrate, methyl-red, and Voges-Proskauer tests gives valuable information supplementary to the Clemesha classification and may give further information as to the possibilities of contamination. The grouping of organisms in classes according to their formulæ with all three tests should prove a useful guide. No definite opinion is hazarded that the power to utilise citrate has been acquired in water by organisms originally fæcal in origin. Tentatively it is suggested that when organisms are citrate utilisers and also produce acidity to methyl-red, they may be regarded with suspicion as possibly indicating pollution, though not of very recent origin.

Dr. B. B. Brahmachari deals with a simple method for estimating the available chlorine in bleaching powder samples. Details are given in his paper in our issue for May.

SMALL-POX AND VACCINATION.

A considerable discussion has taken place in our columns with regard to the incidence of arthritis as a complication or sequel of small-pox. G. S. Chawal records arthritis of both elbows following small-pox; T. S. Dakshinamurthi states that arthritis is a not infrequent complication, and may affect the elbows, knees, and hips; whilst P. N. Shah records a case where arthritis of both elbow joints followed small-pox.

Dr. J. W. Tomb discusses the differential diagnosis between small-pox and chicken-pox. He relies on the fact that in chicken-pox the vesicular eruption appears within 24 hours or earlier of the onset of the fever, whereas in small-pox it is delayed until 48 to 96 hours after the first onset of fever. "The differential diagnosis of chicken-pox and small-pox by means of the time interval elapsing between the date of onset of the fever and the date of outbreak of the eruption" he writes, "is accurate, simple, and unambiguous, and should be adopted by all public health authorities, since any intelligent subordinate can thus make the diagnosis quickly and accurately." This is contested by Khan Bahadur N. H. Choksy, who considers that Indian patients can only rarely state when fever first appeared, and who relies on the nature of the vesicles, the absence of umbilication, the absence of the papular stage and other signs to establish the diagnosis of chicken-pox; and by S. K. Biswas, who relies on the shotty hardness of the points of eruption in the diagnosis of small-pox.

Assistant Surgeon J. H. Theodore, I.M.D., comments on the treatment of small-pox by intravenous potassium permanganate, doses of up to 10 c.c. of a 1 : 500 solution being given, and experiments carried out both on rabbits experimentally and on human cases of the disease. No toxic symptoms were noticed after the injections, and the maximum dose tolerable is probably higher than that advocated. When given intravenously to rabbits the injections have a definite tendency to abort the evolution of vaccinia virus, whilst in man results are very encouraging. J. M. Ghosh comments on two cases of "alastrim" in Keonjhargarh Jail; both were intramural cooks in the jail, and it is difficult to see how the infection was contracted; in the first case daily crops of pustules appeared for 14 days, whilst both patients were only slightly febrile and both were susceptible to vaccination after recovery. The second patient was treated with injections of citrated blood from the convalescent first patient.

Dr. C. W. F. Winckel deals with the organisation against small-pox in the Netherland East Indies. Here results are truly amazing. As his diagrams show small-pox, from being a disease of major importance in the islands, has now almost become insignificant. The essentials are an adequate supply of virulent animal vaccine; qualified and trustworthy vaccinators; constant and intensive supervision by whole time health officers; co-operation on the part of everyone concerned; and a well planned system of vaccination and re-vaccination. Both vaccination and re-vaccination are compulsory by law; in Batavia the number of cases of small-pox in a population of 2,800,000 has decreased from 2,446 in 1914 to nil in 1925; in Bantam from 179 in a population of 900,000 in 1916 to nil in 1925; in Cheribon, with a population of 1,800,000 from 1056 in 1915 to 13 in 1925; in West Java with a population of 9,600,000 from 4,050 in 1919 to 38 in 1925 and 33 in 1926. These figures speak for themselves, but legal powers under the Indian Acts are unfortunately very much more restricted than those in the Dutch East Indies.

Lieut.-Col. J. Cunningham notes on the progressive degeneration of vaccine lymph on continued sub-passage through the same type of vaccinifer (calves). At the 1st, 2nd, 4th and 6th removes there is a definite increase in yield, but with successive removes there is a gradually increasing failure rate. It is obvious, therefore, that if a lymph of the highest potency is to be maintained, Nejland's original process of strict alternation of vaccinifers—rabbit, cow, buffalo—must be adhered to. Weight of pulp yield is not always a reliable guide to the potency of a lymph.

Dr. C. G. Pandit believes that the virus of contagious epithelioma of fowls, when passed in succession into calves and monkeys, can ultimately be converted into vaccinia virus. With calf passages alone such development was not effected, and the interposition of a monkey (*Macacus sinicus*) was necessary. The virus reacted

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

negatively on both the skin and cornea of rabbits, but, as development proceeded lesions appeared at first on the cornea and later on the skin.

RABIES.

In our editorial in July, we attempted to deal with some of the more outstanding problems in rabies, quoting a very interesting letter from Dr. Turkhud. This has brought us two interesting replies. In our issue for October, Col. Cunningham, from the Pasteur Institute of India, Kasauli, records a clear and authenticated case of hydrophobia in man contracted eight months after the patient had been licked on abrasions on the hands by a rabid buffalo. This case appears to settle two important points: that infection can be acquired from the saliva of rabid herbivora, and that it can be acquired by contact of the saliva with abrasions only. The victim was a mason by trade and his hands were continually cracked. In our issue for December, L. F. Henriques, records the case of a person bitten by an apparently rabid camel, who had only one injection of anti-rabic vaccine, but escaped hydrophobia, whereas other persons bitten by the same camel, died from that disease. This, however, appears to be an instance of accidental escape from infection.

In the *R. A. M. C.* Journal, Capt. S. J. L. Lindeman, R.A.M.C., discusses the difficulties in the differential diagnosis between rabies and the nervous forms of distemper in dogs. Both diseases are very prevalent in India. In May, 1926, he had in his bungalow a cocker spaniel with two puppies out of a litter of ten, of which the eight others had been sold, and a fox terrier; all the dogs being well looked after, and it being certain that none of them had been bitten. On May 22nd, one pup had an epileptiform fit, frothed at the mouth, and thereafter had symptoms stimulating rabies, during which it wandered away and when recovered showed paralysis of the extremities. It was destroyed on the 30th May, and on examination at Kasauli, it was reported that Negri bodies were found in the brain sections. The second pup took ill with vague abdominal symptoms in June, and was also destroyed, although apparently healthy. No Negri bodies were found. A third pup of the same litter, which had been sold, took ill with fits at the end of June, and died on July 20th, on the 22nd day of disease; Negri bodies were found. The two adult dogs escaped all symptoms, but in the meantime all persons in contact with the first pup had undergone anti-rabic treatment. The question for solution is: Was this rabies or nervous distemper? Further, was antirabic treatment necessary? Also the incident led to the destruction of valuable pure bred dogs. We are afraid that in our present state of knowledge no definite answer can be given. Negri bodies occur in conditions other than rabies, but in very sparse and scanty numbers, whilst "suspected rabies" is usually considered enough to go upon to advise a course of prophylactic inoculations. Personally, we have given up keeping dogs in India, owing to their frequent exposure to infection with rabies, whilst we should not dream of undergoing antirabic treatment unless bitten by an animal which it was reasonably probable to state definitely was suffering from rabies. Some 90 per cent. of European patients at Pasteur institutes in India are to-day probably treated unnecessarily; the difficulty, however, is to say who is or is not at risk. With the Indian patients matters are totally different, for the vast majority of them are very definitely at risk.

The value of an etherised vaccine in prophylaxis against rabies is being investigated at Kasauli, and in the July issue of the *Indian Journal of Medical Research*, Lieut.-Col. J. Cunningham, Assistant Surgeon M. J. Nicholas, I.M.D., and Military Sub-assistant Surgeon, B. N. Lahiri, I.M.D., continue their investigation into this problem. With street virus brains subject to ether the virus may still be infective up to 72 hours of immersion; after this period the evidence for the persistence of living virus depends upon deaths which might have been due to an attenuated virus (or, possibly, in the reviewer's opinion, to a neurolytic response to inoculation of normal brain matter). If these latter deaths are to be admitted, then it must be admitted that virus exposed to ether may still be infective after 120 hours immersion but is killed after 144 hours' immersion. Street virus is far more resistant to ether than fixed virus, and the results in general tally with those recorded by observers in Europe.

Lieut.-Col. A. G. McKendrick, I.M.S. (retd.), continues his series of reviews of recent literature on rabies in the *Tropical Diseases Bulletin* for the year, a most valuable set of articles whose perusal is essential for information and reference to every worker on the subject, whether in temperate or tropical zones. The series is accompanied by a very full and complete bibliography, which lends its especial value.

OBSTETRICS, GYNÆCOLOGY, INFANT WELFARE.

Dr. Margaret Balfour, W.M.S., India, very kindly contributes the following notes.

A general review of recent advances in obstetrics and gynæcology appeared in the February 1927 issue, by Lieut.-Col. V. B. Green-Armytage. This deals with the various troubles met with in India during pregnancy and labour, such as heart failure, tuberculosis, pernicious anæmia, post-maturity, non-dilatable os, intracranial birth injuries, and antepartum hæmorrhage. It emphasises the importance of preventive medicine in obstetrics in India, and especially of ante-natal care. The author considers that the diet of pregnant women in India is often very deficient in vitamines, that this lowers their resistance to infection, predisposes them to infection after delivery, and renders their infants weak. For puerperal sepsis he recommends Hobb's treatment by intra-uterine injections of glycerine.

In dealing with gynæcology, he speaks of myomectomy for fibroids, hæmorrhagic ovarian cysts, variococele of the round ligament and uterine prolapse. He speaks of the necessity of a sense of pre-operative responsibility for gynæcologists in India, where patients so often come after considerable delay. There should be careful history taking and complete physical examination, including a renal function test. In important and elective operations a salt-free diet should be taken for ten days beforehand, and meat avoided.

In the issue for May, the same author contributes a special article on pelvic inflammatory diseases and pyosalpinx. During five years 13.6 per cent. of the out-patients attending the Eden Hospital, Calcutta, suffered from tubo-ovarian disease; 269 abdominal operations were performed, with a mortality of 6.3 per cent.; 250 patients were discharged cured and 19 died. Operation is not always required in such a large proportion of cases, as many patients recover under medicinal treatment. In India, however, patients come late and are often unwilling to remain long in hospital; hence more operations are performed than in the West. Clinically cases are divided into those due to gonococcal infection—80 per cent., and those due to streptococcal infection—20 per cent. He concludes by detailing advice as to surgical procedures in such cases.

In the issue for November, Col. Green-Armytage gives a most careful and valuable account of prolapse of the uterus. No less than 560 cases were seen in the out-patient department of the Eden Hospital, during the last five years, of which 245 were admitted for operation. The operations carried out were vaginal, with a percentage of 97.5 per cent. of cures, 0.8 per cent. relieved, and 1.7 per cent. deaths. The article is illustrated by a series of sections and diagrams, which includes the pelvis of quadrupeds as well as of man, and some particulars of treatment by the ancients are given. Present day treatment is discussed in detail, both as regards prevention and cure. Illustrations show the value of position and exercises. Readers are warned against the abuse of the pessary so frequent in India, and the different cutting operations are described.

In the issue for December, Col. Green-Armytage deals further with occipito-posterior presentations in labour. This condition appears to be far more frequent in practice in India than in England, and the fœtal mortality is some 20 per cent. as against 10 per cent. in the United Kingdom. The condition is often carelessly or

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ignorantly overlooked until "something has to be done"—that "something" only too often spelling disaster. The essential points in diagnosis are often non-engagement of the head, or when the head is engaged a tennis-ball-like prominence—the fœtal head—to one or other side of the pubic junction; an entire loss of resistance to the examining hands between the pubis and umbilicus, due to the anterior shoulder being well away from the middle line; and, above all, premature rupture of the membranes. If the case be seen before or in the early stages of labour, provided the head of the child is not overlapping the brim of the pelvis (and therefore an obvious case for Cæsarian section) the midwife should apply a Buist pad under doctor's orders, and details for this application are given. If seen in the first stage with strong pains and the membranes intact, morphia and scopalamine should be given and the bladder and rectum emptied. If the membranes have ruptured and with a non-dilated cervix, the Polak method of plugging the cervix with gauze soaked in glycerine may be worth trying. If the membranes have ruptured a long time previously and the fœtal heart sounds are below 110 per minute, a live fœtus cannot be delivered, and in such cases a cranioclast should be applied to the head, a weight extension of 4 lbs. applied to it by a string hanging over the end of the bed, and the patient thus left to deliver herself. If labour is advanced, patience is the wisest procedure, and in certain cases manual rotation may be applied. In these cases, the use of the de Lees' head stethoscope is very useful, for it enables one to listen to the fœtal heart sounds without soiling the hands. Such complications as rupture of the uterus are discussed, and the treatment of shock by intravenous injections of 10 per cent. glucose solution with injections of insulin. In India in general, however, the chief necessity is to train midwives to recognise the occipito-posterior presentation, so that they can at once report cases to the attending doctor, or have the patients conveyed to a suitable hospital.

Eclampsia.—The April number contains an interesting article by Lieut.-Col. C. A. F. Hingston and Dr. A. Lakshmanswami Mudaliar on eclampsia as seen in four years' work at the Madras Maternity Hospital, from January 1922 to June, 1926. During this period 220 cases of eclampsia were seen, an incidence of 1.73 per cent. amongst patients admitted. The condition was 4.5 times as frequent amongst primiparæ as in multiparæ. It always occurred during the second half of pregnancy, but tended to occur earlier among the multiparæ than among the primiparæ. The highest blood pressure reading was 220 mm. of mercury, the lowest 55; and the higher the blood pressure the greater the number of fits and the higher the incidence of coma. Albumin was present in the urine in 89 per cent. of the cases. The fits occurred during labour in 46.8 per cent. of cases, before labour in 27.6 per cent., and after labour in 25.5 per cent. Treatment was directed towards reducing the blood pressure; for this veratrone, 1 c.c., was given subcutaneously if the pressure was above 140 mm., or ½ c.c. if it was below it. Two doses were usually sufficient. This line of treatment is also useful in prophylaxis. Morphia was also given in doses of from ¼ to ½ grain, but after commencing the veratrone treatment less morphia was required. Accouchement forcé was never called for. Twenty-two deaths occurred, a mortality of 10 per cent.; and 64.3 per cent. of the infants were born alive.

A second paper by the same authors describes the treatment of *puerperal sepsis* as carried out in the Madras Maternity Hospital. Drainage and postural treatment are used, but curetting is never done. Anti-streptococcal serum was found valuable as a prophylactic, but was not of much use when sepsis had set in. Stock vaccines gave poor results. The value of autogenous vaccines was doubtful, owing to the delay in their preparation. A polyvalent vaccine was being tried. Bacteriological analysis showed that hæmolytic streptococci were responsible for most of the serious and fatal cases. The only other organism isolated in septicæmic cases was the *B. coli communis*. The vaginal douche may be of value in cases of sapræmia, but the intra-uterine douche is perhaps positively harmful and its use is hardly ever free from risk. An analysis of the bacteriological findings in such cases by Assistant Surgeon, J. H. Theodore, I.M.D., shows the overwhelming importance of hæmolytic streptococci in the causation of puerperal sepsis in India. Over 64 per cent. of cases yielded cultures of streptococci, some 6|7ths of which were of hæmolytic type. On the contrary, examination of the vaginal flora of normal healthy pregnant women yielded a streptococcus only in one patient out of twenty-one examined.

Anæmia of Pregnancy.—The pernicious anæmia of pregnancy, as a disease especially encountered in India, continues to attract attention. Suspending for the moment Dr. Balfour's review of the year, we must pay a word of praise to her most valuable article on this subject in our issue for September. This summarises her findings in 426 cases reported on, in answers to a general questionnaire, and in 150 cases which she investigated personally in Bombay. The disease is not unknown in Europe, but is so very rare that it constitutes a curiosity instead of a commonplace as in India. Pyrexia is a usual accompaniment; enlargement of the spleen was present in 18 per cent. of cases, and œdema was a constant phenomenon. Diarrhœa was present in 38 per cent. of cases, vomiting (of degree more severe than the normal vomiting of pregnancy) in 40 per cent., sore tongue in 31 per cent., and epistaxis in a few cases. The pulse was invariably rapid. The disease was most prevalent in patients of from 20 to 40 years of age, and the incidence greater in multiparæ than in primiparæ. The communities affected, possible seasonal variation, blood state, urinary and fæcal findings are analysed, and an account given of findings at post-mortem examination. Delivery is usually premature and the majority of infants (68 per cent.) are either stillborn or die within two days of birth. On the other hand, a peculiar fact is that infants which survive are normal, and that the affected mothers after delivery tend to make a most rapid and complete recovery, although the condition may recur in a subsequent pregnancy and prove fatal.

What is the causation of this disease which plays so important a part in midwifery in India? The patients chiefly affected are not necessarily those of poorer classes, and women workers in the mills are relatively free from it, whilst those who are compelled to lead a sedentary life are more subject. It is a disease of the cold weather rather than of the hot weather. The children, when they survive, are not affected. It is not due apparently to malaria, nor to dysentery, nor to hook-worm infection, whilst it has no special association with puerperal sepsis. Is it a toxæmia: either from the intestine, or from the products of conception? It is essentially a disease of the second half of pregnancy and a toxic origin would fit in best with the facts. (In this connection the notes above on the anæmia of males in Bombay as an expression of intestinal toxæmia may have some bearing.)

Whatever the facts underlying this most important disease of pregnancy in India, the condition obviously deserves very full investigation. Dr. Balfour is to be congratulated on her careful and extensive study of the condition, and the Indian Research Fund Association on securing the services of so well-trained and experienced an honorary worker in investigating the problem.

The pernicious anæmia of pregnancy is not confined to Bombay, for it is just as prevalent in Bengal, as an analysis of 42 cases seen at the Eden Hospital, Calcutta, by Major S. A. McSwiney assures us. Full details of these cases are given. The incidence in Calcutta works out at 1.7 per cent. of patients admitted. Hindus predominate, and the maternal mortality was 35 per cent. and the fœtal mortality 56 per cent. Over 30 per cent. of cases were among primiparæ, and the earlier the pregnancy the greater the liability to the disease. The condition is five times as common under the age of 30 as after that age; albuminuria is not a marked sign, though œdema is usual, and a tendency towards miscarriage or premature birth very marked; in fact it is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

unusual for a case to proceed to full term. The ordinary causes of severe anæmia, such as malaria, ankylostomiasis, kala-azar, can be excluded as the result of laboratory investigation. Syphilis may be a factor in some cases, and where a positive Wassermann reaction is given, anti-syphilitic treatment is often efficacious; but specific disease will not account for all cases. By way of treatment iron and arsenic, which seem to be assimilated better when given by subcutaneous injection rather than orally, are advised, a liberal diet, sunshine, and vitamines, whole blood transfusions, and where the Wassermann reaction is positive full anti-syphilitic treatment.

The paper concludes with a full discussion on this mysterious disease of pregnancy. Up to date there have been no biochemical investigations of the disease, so far as we know. Feeding on nearly raw liver is a most useful measure in conditions of very grave anæmia in males, and might prove useful in the pernicious anæmia of pregnancy. It is at least clear that the ætiology of the disease should receive thorough investigation, since it is of such great importance in midwifery practice in India. Even from the mofussil J. N. Ghosal in our issue for May speaks of it as a relatively common disease; about 25 per cent. of cases die during labour, another 50 per cent. within a week after delivery—usually in a condition of intense dyspnœa; whilst some 25 per cent. recover spontaneously after delivery; and death in a subsequent pregnancy is very common.

Dr. Margaret Balfour deals with the maternal mortality in childbirth in India in a special article in our issue for November. Particulars with regard to 11,343 cases of labour were received from large hospitals in different parts of India, and the results analysed and compared with similar figures for British hospitals. From this it appears that there is considerably more disease in pregnancy in India than in Britain. The anæmia of pregnancy and osteomalacia, so frequent in India, are practically unknown in Britain. Fewer cases enter hospitals in India for accidents of labour and delayed labour, probably on account of the lack of a proper midwifery service. The mortality in all classes of cases is higher in India. "The nature of the mortality is largely due to obscure diseases," she writes. "Careful medical research is needed to discover the causes and means of prevention of these diseases. As at least two of them are nearly unknown in Britain, medical practitioners who come out to India from that country are unacquainted with them and little attention is paid to them in Indian medical schools and colleges. Instruction in the diseases of pregnancy in tropical countries should form part of the curriculum of all schools of tropical medicine." Registration of *dais* and midwives, arrangements for their suitable inspection, should be enforced, and much more attention paid to the providing of ante-natal clinics. The purdah system appears to exercise a very prejudicial influence on pregnancy, but even in the most educated classes in India the mortality in childbirth is more than double that in England.

In addition to the above papers a number of individual case accounts have been published during the year, but do not call for special comment. The country *dai* and her ministrations are luridly commented on by T. N. Chakravarty in a letter in our issue for April; cases where hands or limbs have actually been pulled off the presenting fœtus are not uncommon; and the writer asks how long India is going to put up with such "barbaric midwifery."

A note on *Appendicitis in Indian Women* by Drs. Campbell and Patel gives details of the pathological investigation of 25 appendices operated on at the Lady Hardinge Hospital, Delhi. Of these 14 contained concretions and 23 contained fæcal matter. Cultures gave a growth of *B. coli*. One appendix only showed tuberculous infection.

CHILDREN'S DISEASES AND WELFARE.

An extremely interesting paper is one by Dr. G. A. C. Gordon in the *Journal of Tropical Medicine and Hygiene* on the health of European children in Malaya, and what he writes about Malaya applies with the same force to India. He combats the almost universal belief that European children should not be brought up in the tropics. "Taking into consideration certain peculiar advantages (of Singapore) as compared with other tropical countries, given good ante-natal and post-natal treatment, strict parental control and supervision of food and general welfare, and intelligent preventive and early curative measures, the European child could thrive and flourish, and continue to reside in Singapore and Malaya for a much longer period than is the case at present." He considers that European children could do well in Malaya up to the age of 9 years at least. At birth the European baby in the tropics is just as healthy and vigorous as those born in England. Up to the age of 4 or 5 the mortality rates are actually lower than the corresponding ones in Britain, owing to the rarity of certain zymotic diseases in the tropics, whilst tuberculosis and rheumatism have not to be faced. The "nervous child," however, is probably commoner in the tropics, whilst there are moral dangers to contend with. He considers that breast feeding is of great importance in the case of European children in the tropics; he prefers buffalo or goat milk to that of the cow in the tropics, since it is more nutritious. The unsweetened condensed milks are very good, and he quotes a dictum of Deeks, that "to judge from the reports received, lactogen seems to have solved the problem of infant feeding in the tropics." With the gradual passage to a child's diet, the most stringent supervision of foodstuffs and the kitchen are essential. The mother as a rule tends to overclothe her child. Many European children in the tropics get too little exercise. Within moderation a European child can play at any hour of the day except during the heat of the afternoon. Singapore offers special advantages for the learning of swimming. The chief foes of the European child in the tropics are gastro-intestinal ailments, skin affections, and helminthic infections, and all these can be guarded against or cured. The paper, as a whole, is a most interesting one, and full of sound advice.

Infantile Cirrhosis.—This mysterious disease continues to attract attention, and is dealt with in our issue for March by M. A. K. Iyer. He stresses the frequent finding of syphilis in the parents; too much starchy and fatty foods as a possible factor; and the possible rôle of patent foods. Whilst most common among Brahmins and high caste Hindus, it is curiously absent among the Brahmins of Malabar.

OPHTHALMOLOGY.

Once again we are indebted to Lieut.-Col. R. E. Wright of Madras, for his review of the year, which is as follows:—

Sir Norman Walker's report deals with the teaching of ophthalmology in India in a highly complimentary manner. In this connection, it may be noted that an attempt to encourage the post-graduate study of this subject has been made in Madras, by the establishment of an examination in the teaching and practice of the Government Ophthalmic Hospital. It is based on the lines of the L. M. Rotunda, Dublin, and successful candidates are granted the certificate of L.O.

The subject of *cataract* extraction again looms large amongst contributions from workers in India.

Col. Smith published one of his most important recent articles on this subject. He traces the history of intracapsular extraction, crediting Col. McNamara, I.M.S., with its origin. To Smith, however, belongs the honour of having established and popularised the idea, so that at present it is employed by some surgeons all the world over, with variations for the most part from the Smith procedure, such as Stancelaneau's forceps extraction modified by Knapp, and phakoerisis developed by Barraquer. Smith regards all methods as inferior to his and believes that by his new technique he can insure even the hard lens tumbling with a degree of success "beyond his expectations."

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

B. N. Bhaduri records phlyctenular conjunctivitis recurring with successive menstruations. The same author draws attention to a possible case of cataract due to kala-azar, but Col. Coppinger in a footnote evidently considers this ætiology doubtful.

Gopal Tambe describes an interesting case of symmetrical tumefaction of the lids in a child, the nature of which was not determined.

In his Annual Report of the Government Ophthalmic Hospital, Madras, Col. Wright discusses cataract work in some detail, dealing with such points as the prejudicial effects of blood, cortex, capsule, or organisms in the anterior chamber. Blocking of the main trunk of the facial nerve, employed there originally in 1921, has become a routine in troublesome patients. Ciliary ganglion blocking is for the most part reserved for painful eyes. Phakoerisis with special reference to Green's modification of Barraquer's technique, and some of the essentials of the problem capsolotomy *versus* intracapsular extraction, are dealt with. The author is inclined to favour phakoerisis in selected cases, while still maintaining a firm conviction in the undesirability of vitreous trauma. The bacteriology of iris tissue was the subject of a research undertaken with the aid of Mr. Theodore, under the auspices of the King Institute, Guindy. The problem is a very important one and those interested will find food for thought in the details published. The relation of glare to the frequency of cataract is touched on, hospital records unfortunately do not appear to be of statistical value in this problem. A simple method of dealing with destructive lesions of the lids as an aid to the general practitioner is described. Uuguentum hydrarg. perchloride, 0.5 per cent., is suggested as a treatment for trachoma of general applicability. Interesting clinical cases referred to in the report include myiasis of the degenerate cornea, bilateral lymphoblastoma of the orbit with leukæmia showing cell inclusions, uncommon orbital tumours, and congenital ankyloblepharon.

Major Duggan records his impressions of Green's visit to Bombay, and is favourably impressed with deep infiltration of the orbit as employed by him. (The conception, however, is not Green's, having been introduced in Elschnig's clinic in 1908 and utilised in many places including India since.)

G. J. Gnanadikam, writing from Keugelberg's clinic, Tirapatur, describes the preparation of patients for cataract operations by means of yellow oxide ointment. The method is important and finds considerable favour. Other details of Keugelberg's technique are worthy of attention. It may be noted that he uses the suture control of the superior rectus.

Major Cruickshank publishes an important analysis of work done in Holland's clinic at Shikarpur. From this careful survey may be obtained a comprehensive picture of cataract work in general and its evolution in particular directions, in this representative cataract centre of the North.

Col. Wright and Koman Nayar presented a corneal microscope study of a series of intracapsular extractions with Green's apparatus before the Oxford Congress, featuring in particular the behaviour of the vitreous body.

Major Dick and the writer spent some time at Barraquer's clinic and were privileged to observe his methods.

Possibly the most far-reaching event of the year is Noguchi's work on trachoma. He has isolated an organism from human trachoma cases which, from culture, produces a condition in chimpanzees (and *Macacus rhesus*), indistinguishable from human trachoma in its early stages. Direct transmission from man to monkey is impossible, but monkeys infected on one side transfer the disease to the sound eye. The writer, whilst on a visit to some of the leading clinics in the Eastern States of America, had the privilege of discussing this important research with Dr. Noguchi at the Rockefeller Institute, New York, and seeing his experimental monkeys and histo-pathological preparations. It is reasonable to hope that at last a decided advance has been made in the elucidation of this important disease, which has been a world-wide scourge of great economic importance for centuries.

In connection with ophthalmology, we may perhaps call the attention of those of our readers who do not know of them to the excellent series of special reviews of recent work in the subject, published from time to time by Lieut.-Col. H. Kirkpatrick, I.M.S. (retd.) in the *Tropical Diseases Bulletin*.

PHARMACOLOGY.

A very considerable number of papers have here to be considered, chiefly from Lieut.-Col. R. N. Chopra's department at the Calcutta School of Tropical Medicine, showing how constantly increasing is the work in that department and its value to Indian pharmacology.

Major (as he then was) Chopra presided over the Medical and Veterinary Research section of the Indian Science Congress in January of the year, and his presidential address on "Some aspects of therapeutics in India" was published in our issue for March. It is a most interesting and thoughtful review of the present status of therapeutics and pharmacology in India; and one which we would commend to the attention of our readers.

Antimony.—Major Chopra records the results of an investigation into the action of the organic compounds of antimony. The following are his conclusions.

(1) All the organic compounds of antimony produce a fall in the systemic blood pressure after intravenous injections. This fall is easily compensated for when small doses are injected but if large doses are given and specially if given rapidly, the fall is pronounced and lasting. The blood pressure soon regains its normal level unless very large doses have been injected.

(2) The fall in the systemic pressure is due partly to the lessened output of the left ventricle and partly to dilatation of the splanchnic vessels. The acidity of the solutions is not an important factor in producing the fall.

(3) The cardiometer shows that the heart is considerably dilated and both the force and the amplitude of the contractions are decreased. This weakening of the beats is also shown by the myocardiograph and in records of the contractions of the isolated heart.

(4) The pressure in the pulmonary artery and also in the inferior vena cava rises. With small doses, given slowly, the rise is small and is immediately compensated for. With larger doses, given rapidly, the pulmonary pressure increases 100 per cent. or more and persists at that level for some time. This rise is due to progressively increasing obstruction in the lungs which causes the right heart at first to do more work and then to dilate when the strain is beyond its power. At this time the systemic pressure has fallen and the venous pressure rises.

(5) The blood vessels of the intestines, liver and spleen dilate; the kidney shows slight contraction, and the limb also slightly decreases in volume.

(6) The increase in the size of the spleen and liver after injections is very remarkable; the rhythmic movements of the spleen are increased. The influx of a large amount of blood into these organs is probably an important factor in the curative effect of these compounds.

(7) The respiration is only slightly stimulated even with large doses of the tartrates, but with large doses of the organic compounds it stops immediately with the fall in blood pressure. Respiration becomes irregular, shallow and jerky and changes from the abdominal type to a thoracic type. When large doses are rapidly given both the heart and respiration may stop simultaneously.

(8) The circulatory changes in the pulmonary, systemic and venous systems and the changes in the circulation of the spleen, liver, etc., account for all the milder toxic symptoms such as faintness, feeling of constriction in the chest, cough, feeling of fulness in the region of spleen and liver, etc. The severe toxic symptoms such as dyspnœa, cyanosis, marked respiratory disturbances resembling "nitroid crises" are associated

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

with extreme changes in the pulmonary pressure as well as contraction of the bronchi.

The effect of antimony salts on conception and pregnancy in experimental animals has been studied by Lieut.-Col. E. C. Hodgson, Dr. A. C. Vardon, I.M.D., and Subadar Zorawar Singh, I.M.D. They conclude that there is definite evidence that antimony salts cause damage to female animals which are receiving periodic injections, the damage being responsible for either failure of conception, abortion, or damage to the fœtus, and frequently in all three ways. The injury passes off very rapidly as soon as the antimony injections cease. There is no evidence that antimony injections have any effect in causing sterility in the male.

Cinchona derivatives.—Major T. A. Hughes and Mr. D. L. Shrivastava, M.SC., have studied the effect of quinine administration on the phosphorus metabolism in man. Their conclusions are as follows:—

The results show that quinine in anti-malarial doses in man causes a retention of phosphates. Considered in the light of previous work this fact is evidence of the interference of this drug with carbohydrate metabolism, and as quinine in the doses mentioned has been shown to cause a fall in the blood-sugar, one may venture to conclude that this interference takes the form of causing an increased output of insulin. The work of Brittin, who showed that stimulation of the right vagus in cats produced a fall in blood-sugar when the circulation, through the pancreas, was unaffected, and that of Clarke, who produced hypoglycæmia in rabbits by the injection of vagal stimulants, indicate that quinine produces its effect on the circulating glucose by acting as a stimulant of the parasympathetic system. While the fall in blood-sugar after administration of quinine can be prevented by previous ingestion of carbohydrates, as has been pointed out elsewhere, this does not prevent, but rather tends to augment the effect on the islet tissue. When, therefore, quinine is administrated in large doses over long periods, as is often done in the treatment of malaria, it is acting more or less continually as a stimulant of the pancreatic islets and as over-stimulation of this tissue is known to produce exhaustion it is not unlikely that in many cases quinine plays a rôle in the production of a diabetic condition.

Major Chopra and J. C. David have studied the pharmacological action of quinamine. This occurs in appreciable amounts in Indian cinchona bark, but has but little action on bacteria and protozoa. It does not affect the digestive ferments to any marked degree, but stimulates intestinal peristalsis, and on intravenous injection causes increase in the splenic volume. It has a weaker action on the circulation than the other alkaloids of cinchona bark; the respirations are slowed and there is slight but persistent dilatation of the bronchi. Its action on both the virgin and pregnant uterus, however, is exceedingly marked, and in a dilution of 1 : 500,000 it causes marked tonic contraction of that organ. It is possible that the oxytoxic action so often attributed to quinine is due to traces of quinamine in the drug. The anæsthetic action of quinamine on the cornea and in blocking impulses in nerve trunks is almost as marked as that of cocaine.

Alcohol.—Major Chopra deals with the toxicity of mature and immature genuine spirits and of imitation or factitious spirits on the Indian market. His conclusions are as follows:—

The data I have gathered from these experiments lead me to conclude that—

(1) Ethyl alcohol by itself is at least as toxic to cats as ethyl alcohol *plus* the essences used in preparation of the imitation or factitious spirits. These essences consumed in quantities largely in excess of those ever found in the potable imitation spirits produce little or no effect on the animal organism.

(2) The specimens of fully mature and immature genuine spirits and the imitation or factitious spirits showed about equal toxicity towards cats when given in moderately large doses, such as are usually consumed by man, and also in toxic doses. The organs which bear the main brunt are the gastro-intestinal tract, the liver and the kidneys (as in man) and the degree of injury was about equal in all cases.

(3) My investigations confirm the work of the previous workers that ethyl alcohol is mainly responsible for the toxic effects produced, the bye-products even when consumed in amounts far in excess of those present in the immature spirits have little or no effect on the animals' organism.

(4) The deleterious effects of the cheaper spirits are due to the tendency on the part of the consumer to ingest larger quantities of these liquors, partly, because of their low cost and partly because of their comparatively milder taste which is less satisfying to the palate. Larger quantities of ethyl alcohol are therefore consumed and the toxic effects are attributable to that rather than to the bye-products present as a result of the spirits being not fully matured. The imitation spirits are made from patent still-spirits which contain only minute traces of the bye-products and to which the term immature cannot be applied.

Dr. B. B. Brahmachari deals with the germicidal power of ethyl alcohol in spirits in a paper read at the Indian Science Congress. In India, country spirits are frequently diluted with water which is freely open to gross contamination, hence this question becomes important. The cholera vibrio does not stand 11.8 per cent. of alcohol and is killed within 24 hours by 7.8 per cent. of alcohol, equivalent to a strength of 86 per cent. under proof. The *Bacillus typhosus* is more resistant, but is killed at 80 per cent. under proof within 24 hours. To kill dysentery bacilli (Flexner type) a strength of 15·75 per cent. of alcohol, or 72·5 per cent. under proof is necessary. In general, it may be said that the strengths of country spirits issued are such that the amount of alcohol present will sterilise the solution of bacteria, but in Bihar and Orissa strengths of 80 and 85 per cent. under proof are official and these may harbour infectious organisms.

Indian Indigenous Drugs.—Here two papers call for remark. Major R. N. Chopra and Mr. N. R. Chatterjee, M.SC., deal with the pharmacological actions and therapeutic use of *babchi* (*Psoralia corylifolia*), the oil of which is much used in the treatment of leucoderma. Their conclusions are as follows:—

(1) The active principle of the seeds of *Psoralia corylifolia* (*babchi*) is an essential oil. A fixed oil and a resin occur in large quantities but these are not pharmacologically active substances. Traces of a substance of alkaloidal nature are also present.

(2) The essential oil has a powerful effect against the skin streptococci. It has a specific effect on the arterioles of the sub-capillary plexuses; these it dilates so that in this area plasma is increased. The skin becomes red, the melanoblasts are stimulated leading to pigment formation. This pigment is exuded and diffuses into the decolorised leucodermic patches.

(3) Local applications of the oleo-resinous extracts made from the seeds are beneficial in the treatment of cases of leucoderma of non-syphilitic origin. If affections of the gastro-intestinal tract such as *E. histolytica* infections, etc., are present, these should be treated at the same time.

In a special *Indian Medical Research Memoir* (No. 6) the Rev. Father J. F. Caius, and Dr. K. S. Mhaskar of the Haffkine Institute, Bombay, contribute a study of the well known Indian remedy for dysentery, *kurchi* or *Holarrhena antidysenterica*. They conclude the bark has a much more anti-dysenteric action than the seeds. Doses of up to 60 to 120 grains of the powdered bark may be administered daily with safety, but an alcoholic extract is better, since 55 per cent. of the powdered bark consists of inert substances. The anti-periodic property of the plant requires fuller investigation. It is neither anthelminthic, nor stimulant, nor astringent, nor styptic. It is a bitter which increases appetite and digestive power. Its anti-dysenteric value compares favourably with that of any of the drugs now in vogue. Its anti-diarrhœal properties are not dependent on any one chemical constituent, but seem to be associated with the entire seed or bark. Finally, "it affords a safe.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cheap, reliable, and easily administered drug for the treatment of diarrhœic troubles." Will the big manufacturing chemical firms of India please take note? For here is an Indian remedy for diarrhœa and amœbiasis which appears to be efficient, easily administered, and far cheaper than emetine.

Drug Addiction.—Major Chopra and K. S. Grewal have made a special study of the opium habit in India, their enquiry having been conducted chiefly among the Sikh population of Calcutta. Their conclusions are as follows:—

(1) In this series of cases, the commonest cause of opium taking was the association with and example of other addicts. Disease came next as a cause.

(2) The majority (85 per cent.) of addicts started taking opium before 40 years of age.

(3) 59 per cent. took more than ten grains a day and 85 per cent. over 5 grains a day.

(4) The younger addicts showed a greater tendency towards taking larger doses than elderly persons.

(5) Those who acquired the habit later in life remained satisfied with comparatively small doses.

(6) The habit is easily acquired but difficult to break off.

(7) 65 per cent. of the addicts declare that the habit is harmful. They want to give it up but are afraid to do so because of the withdrawal symptoms.

(8) Opium addiction is rare amongst the women.

(9) The withdrawal symptoms are identical with those observed elsewhere.

HELMINTHOLOGY.

Dr. P. A. Maplestone, M.B., D.S.O., Ankylostomiasis Research Worker, Calcutta School of Tropical Medicine, kindly contributes the following review of the year.

Lieut.-Col. Sir Frank Connor drew attention to the large amount of morbidity due to filariasis in India, and he advocates an enquiry on the lines of a commission, as being more likely to produce valuable results than are the present scattered and independent investigations now being carried on.

Three cases of filariasis with fever and glandular enlargement were treated by C. M. Dalal, with some success, it is claimed. Two of the cases received a single injection of 0·6 gm. neosalvarsan, and the third case had two injections of the same drug. Subsequent observation showed that there was no return of fever, and that there was a steady improvement in the glandular condition.

Dr. Vishnu Korke reported the results of a filarial survey of Bihar and Orissa. He found filariasis fairly prevalent in this province, and the chief clinical signs are affection of the genitals. The predominant species of microfilaria was *Mf. bancrofti*, but some of the material examined shows certain departures from the usual morphological picture of this worm in stained material.

The helminthological survey of the whole of India conducted by Asa C. Chandler has been completed. This survey was very rapidly conducted and the total number of persons examined is a very small proportion of the total population. Consequently the conclusions arrived at cannot be regarded as more than approximate, and more detailed investigations would most likely lead to considerable local modification in certain districts. However, speaking generally, the results may be taken as a good bird's-eye view of the position. The general indications are: that with the exception of Northern Bengal, parts of Burma and Assam, Travancore, and the Southern coastal portion of Bombay, hookworm infection is not very heavy, and while not altogether negligible in the rest of India, it is not a morbidity factor of primary importance. In conjunction with the hookworm survey, records were kept of other helminthic infections, whose presence is revealed by the methods of diagnosis used. It was found that *Ascaris* and *Trichuris* infections ran fairly parallel, and that they are common where there is evidence of gross pollution of the water-supply. But they also occur with considerable frequency in places where water pollution is not a factor, notably the tea estates of Darjeeling, the Dooars, Sylhet, parts of Burma, and in the Wynaad District of Southern India. The reason for this did not become apparent, but it was found to be a rule of general application that those districts with a heavy rainfall were the ones in which *Ascaris* and *Trichuris* infections were high, whether there was evidence of gross water pollution or not. But in North-Western India, where there is no provision to prevent fæcal contamination of the tanks, these two infections were rare, and it is suggested that desiccation and direct sunlight, even for short periods, kills the eggs of these species. *Hymenolepis nana* infection is fairly common on the whole, but it is entirely absent from some parts of India and its distribution is quite different from that of the above two worms. Examination of the areas where it is frequent, however, shows a marked coincidence with the distribution of plague; this suggests the rodent origin of the infection and is advanced as epidemiological evidence of the identity of the dwarf tapeworms of man and rodents. This is supported by the fact that *H. nana* infections were commonest in those places where the people were in the habit of keeping cooked food from one day to the next, and were careless in covering it effectually, to prevent the access of rats. *Hymenolepis diminuta* which is essentially a rat parasite was found 23 times in approximately 10,000 examinations, and 22 of these cases were in districts where *H. nana* infections were over 3 per cent., thus lending further support to the view that rats are important reservoirs of worm parasites communicable to man. Eggs of a *Trichostrongylus sp.* were found on a good many occasions, but the distribution was very uneven; eggs of a Gnathostome were found on three occasions in stools that from other evidence were considered to be of human origin, and seven times eggs of an unknown nematode were encountered. Schistosome eggs of an unknown species were found twice in stools that had been collected from the ground. *Tænia saginata* was not found at all in Hindus and was rare in Mahomedans.

N. H. Fairley in two papers, records the results of experimental infections with *Schistosomum spindalis*. In the first paper he shows by post-mortem examinations at stated intervals of experimentally infected monkeys, that they are susceptible to infection, but that the cercariæ after undergoing partial development disappear from the host before reaching maturity, and that the complement fixation test which becomes positive shortly after infection at first rises in titre and then gradually disappears, indicating spontaneous cure. Similar experiments with goats resulted in the recovery of mature worms and eggs from various parts of the animals. The development of the complement fixation reaction in goats, developed at approximately the same rate as in monkeys, but it remained high until their death. This indicates that the serum reaction in monkeys is not evidence of the production of immunity, but that there is some inherent character in their tissues which is a true natural immunity. Human beings probably possess a similar nature immunity against this trematode, since human infection with *S. spindalis* is unknown, despite the fact that the washerwomen of Bombay work in tanks from which heavily infected molluscs have been taken. The second paper deals with the infection of two water buffaloes with cercariæ of *S. spindalis*. These animals were killed 81 and 94 days, respectively, after infection, and in both of them numerous living worms and eggs were found. The development of complement fixation did not rise as high as in the case of the goats and monkeys, but this is considered to be due to the smaller dose of cercariæ relative to the size of the animals. From the habits of the water buffalo it is considered that this animal is probably the true definitive host of *S. spindalis*.

From the Haffkine Institute, Bombay, Colonel Mackie reports further on the work at that Institute on schistosomiasis, as follows:—

Dr. N. Hamilton Fairley and Dr. F. Jasudasen have continued their enquiry on schistosomiasis. Their work is not quite complete to draw conclusions, still it will be of interest to indicate the various problems which have engaged their attention. They have investigated the possibility of transmission of disease in animals by *Schistosoma spindalis* via the upper alimentary canal. Contrary to the case in human beings, they find that animals can be infected by this route. Then they have studied a number of problems in connection with the bilharzial antigen, e.g., whether it is the ether-soluble or the alcohol-soluble' constituent of dried bilharzial infected livers of *Planorbis exustus* which contains the antigenic factor; the effect of heat on this antigen, and the value of an alcoholic extract of an adult schistosome as an antigen. They have conducted experiments to determine whether the immunity developed by the monkey, *Macacus sinicus*, during a first attack is a complete immunity on the therapeutic side; they have tested the relative value of tartar emetic in solution in water and in serum. They have also tested the value of Neostam, or stibamine glucoside (provided by Burroughs Wellcome) in treatment of animal bilharziasis.

In addition to the papers noted on in Dr. Maplestone's review, there are a few others which perhaps call for remark. A. K. Mukerji published a table showing for 1925-26 the incidence of helminthic infections among patients in the Carmichæl Hospital for Tropical Diseases attached to the Calcutta School of Tropical Medicine. All stools are examined by Lane's direct centrifugal flotation method, and also by McVail's thick smear and levitation process. The results in this population are to show a general helminthic rate of infection almost double that for patients at the Calcutta Medical College, published a few months previously by D. M. Chatterji. Whilst hookworm infection is important, *Ascaris* infection is not of much less importance.

Hookworm.—A paper of importance to workers in India is that by Lieut.-Col. Clayton Lane, I.M.S. (retd.) in the *Transactions of the Royal Society of Tropical Medicine and Hygiene*, Vol. XX, p. 455. This is practically a summary of his former series of papers on the mass diagnosis of ankylostome infection, and constitutes a final defence of his technique of direct centrifugal flotation as *the* method for *mass* diagnosis; "individual exact diagnosis on a mass scale has been my unswerving aim over a period of many years," he writes. "It would seem that direct centrifugal flotation approaches it." This paper should be consulted in the original by those who have to carry out examinations for hookworm infection on a mass scale.

In our October issue, A. K. Mukerji dwells on the physical efficiency in persons infected with hookworm. This reports on an application of Schneider's cardio-vascular test for physical efficiency to Indian subjects infected with hookworm and to healthy Indian controls. The results for healthy persons compare favourably with Schneider's figures for America. In general, he concludes, hookworm infestation in this country—as studied in Bengal jails—is not sufficiently severe to cause definite loss of physical efficiency. This finding is of interest, for it clinches a vague similar clinical opinion to which many observers have been coming during recent years.

Dr. Milford Rice records the results of mass treatment for hookworm infections in tea gardens in Assam. His conclusions are as follows:—

(1) Mass treatments for hookworm disease should be given in February and March on tea estates in Assam.

(2) Most newly recruited coolies have hookworm infection when they arrive on tea estates from their respective countries and should be treated upon arrival.

(3) If cattle manure contains active hookworm eggs, heavy infections might be expected through coolies using it as plaster for walls and floors of their houses.

(4) Pigs and dogs certainly, and possibly cattle, by passing their stools in coolie lines after eating human fæces, are a means of reinfection.

(5) Carbon tetrachloride, given in 60-minim doses to adults (18 to 50 years of age) in one ounce of saturated magnesium sulphate solution and after a morning meal, is a safe drug to use in tea estate practice. It is also safe to use for children and the aged if given in proportionate doses.

(6) No precautions are necessary other than to warn patients that they are not to take alcohol or spirits for 24 hours before or after treatment and to treat no case with any liver complaint.

(7) Pregnant women can be given the same dose as other coolies.

(8) The number of infections can be materially reduced by such mass treatments.

(9) Heavy infections can be reduced to harmless ones by such mass treatments.

Ascaris infection in reality appears to be of more pathogenic importance in India than hookworm infection, though the infection is often devoid of symptoms, this is by no means always the case, and the symptoms caused may be severe and even fatal. Further, the infection is extremely common in India. Major J. H. C. Walker, R.A.M.C., records an infestation rate of no less than 85 per cent. in the garrison of Singapore, traced chiefly to the supply of uncooked vegetables from the local market gardens, managed chiefly by Chinese. The use of human fæces as garden manure is forbidden by law, but in practice this practice is very difficult to prevent. The fæces so used are generally stored for three weeks before use, and this gives the *Ascaris* ova time to mature and become infective. Clinical notes of severe cases of infestation follows.

Y. S. Row records a case of *Ascaris* infection with symptoms simulating cholera, completely cured by santonin administration. M. Barooa records two similar cases, where, however, near relatives of the patients were suffering from true cholera at the same time. B. N. Chakravartty gives details of a case of extremely severe abdominal colic accompanied by *Ascaris* infection, and cured by santonin and calomel administration. Finally, M. Barooa records a case where more than 500 worms were present, the patient had all the clinical signs and symptoms of acute intestinal obstruction, was operated on, and died.

It seems not unlikely that *Ascaris* infection is a more important problem in India than hookworm infection, and it would be interesting to get figures for general incidence of the infestation and reports as to its pathogenicity or otherwise.

In our issue for August, P. M. Bhachech records a personal experience of guinea worm infection. Two worms were discharged in 1908 with suppuration; a further worm without suppuration in 1912; and finally a third, very small worm, which first appeared in the eye and was finally discharged through the canthus of the eye in 1927. The patient had been in endemic infected districts, however, during most of his service.

ENTOMOLOGY.

Dr. C. Strickland has very kindly forwarded us the following review for the year.

The papers on medical entomology which have appeared during the year are here classified according to the branches of medicine to which they relate. I am indebted to Dr. Roy for his help in compiling these notes.

Ears, noses and throats.—Biswas and Strickland record and discuss a case of infestation of the naso-pharynx with a polychæte or marine worm in a person accustomed to bathe in the Ganges. The symptoms were of very severe coryza.

Seshachalam has notified a remarkable foreign body of the external ear passage, to wit a small live scorpion about one inch long.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Klein recommends for the removal of ticks from the external ear passage the filling of it with Dioxygen, leaving it for 10 to 15 minutes and then removal of the dead parasite by syringing with warm water.

Beselin records the infestation of the ear passage with the tick *Ornithodorus megnini*. Loubser has made independent observations to the same effect.

Eyes.—Felt mentions a case from which young maggots of the species *Wohlfartia vigil* parasitic on the conjunctiva were removed.

Wright of Madras has described myiasis of the cornea which had showed dystrophic changes. The maggots were hatched out and proved to be flies of the family Phoridæ (*Apiochæta scalaris ferruginea*).

Mazza and Frias report the effects of the vesication of the lower eyelid by a hairy caterpillar.

Venoms, stings, intoxication, etc.—Cases of general toxic effects following the "bites" or "stings" of diverse creatures have been reported and may be given under:—

Bees.—d'Abreu analyses five cases from Lahore and remarks on the diversity of the symptoms produced.

Beetles.—Parlowsky and Stein discuss the toxic properties of the vesicant fluids of *Pœderus fuscipes*, the blister beetle (which produces spider-lick in India). They show that the toxin is mainly to be found in the insect's blood.

Centipedes.—Hase has reported on the venom of certain small European species, whose bite causes more serious local symptoms than constitutional.

Ticks.—Ross reports on experimentally induced tick-paralysis in dogs. Paralysis can only be effected by the adult of the species used, *Ixodes holocyclus*, though young ticks can produce other symptoms.

Spiders.—Bogen in California has described 15 cases of severe intoxication by species of the genus *Lathrodectus*, while Jackson in Queensland reports a fatal case. McKay makes the suggestion that these serious cases should be treated "on the same principles as snake bite." Korownikow gives another account of spider poisoning by a *Lathrodectus*, noting that no local symptoms are produced but very severe and rapid general intoxication. It should be noted that these spiders occur in India. They are small with a globular abdominal division usually marked on the dorsum with one or more brightly coloured spots.

Scorpions.—Milton Lang from the Central Provinces reports a case of scorpion bite. Symptoms appeared within 15 minutes and included urgent desire to micturate not to be satisfied, severe pains throughout the body, vomiting, cough with blood-stained expectoration, cyanosis, loss of radial pulse and cold sweats. Treatment as for collapse restored the patient.

Skins.—Dobronravov has described "a creeping eruption" which was traced to a single larva of a bot-fly living in the foot. Hase has noted the typical and intense erythema following centipede bite. Hoffman from the West Indies describes the irritant effects of *Loxa flavicollis* (a Pentatomid bug) when brought into contact with the skin. da Matta has reported an acute dermatitis followed by a vesicular eruption due to a hairy caterpillar *Megalopyge lenata*. Illingworth has also described a similar condition caused by the hairy moth caterpillar *Nygmia flava*.

D. N. Roy, analysing the local effects of mosquito bites has concluded that the diverticula of the gut are food reservoirs. He finds that an emulsion of the diverticula as well as of the salivary glands will produce erythema and a wheal when injected intracutaneously, the former being more severe. He could find no anticoagulant in these organs.

Pavlovsky and Stein have reported on the pathology of the skin lesions of the vesication produced by the blister beetle *Pœderus fuscipes* (spider-lick).

Affections of the intestinal tract.—Heymons has noted that an Annelid (*Lumbriculus lineatus*) commonly found in fresh water may live as a parasite in the human intestine.

Faggioli mentions a case of a child aged 15 months with a history of intestinal disturbance who passed the rat-tail larvæ of the hover fly (*Eristalis tenax*). Treatment by santonin and calomel cured the patient.

Bedford in South Africa found the larvæ of the stable fly *Stomoxys calcitrans* rather unusually causing intestinal disturbance.

Affections of the genito-urinary tract.—Mekie has described the infestation of the bladder by mites causing cystitis.

Mumford reports from England two cases of myiasis of the tract by *Fannia canicularis* and *Musca domestica* respectively.

PREVENTIVE MEDICINE.

Plague.—Fabian Hirst as a result of much detailed experimental work thinks that the spread of plague among rats depends primarily on *cheopis* though he admits that *astia* may occasionally transmit the infection.

Typhus, pseudo-typhus, etc.—Spencer shows that in Virginia pseudo-typhus follows the bite of a tick, probably *Amblyomma americanum*. In these cases there was a local lesion and Weil-Felix was negative.

Noguchi has found *Dermacentor andersoni* transmit Oroya fever to monkeys and has isolated *Bartonella bacilliformis* from the infected cases.

Stanley Hirst gives a list of 7 species of Gamasid mites which occur on rats and he also gives a key to the identification of the 7 blood-sucking genera. He considers the genera *Dermanyssus* and *Liponyssus* to be the most likely dangers to man in the transmission of infections.

MALARIA.

Anophelines.—Christophers, Sinton and Covell have prepared a key to the identification of the adult Anophelines of India, while Strickland and Chowdhury have done the same for the larvæ. Covell has described a new species *A. ramsayi*, while Strickland and Chowdhury's new species *A. pseudo-jamesi* may be the same.

Chalam has found *subpictus, stephensi* and *culicifacies* breeding freely in sea-water pools in Back Bay, Bombay; and the same author has shown that the eggs of the first two species cannot resist desiccation for more than 12 days.

In addition to those mentioned in Dr. Strickland's review, several other papers call for remark. Many or most of these have appeared in the *Indian Journal of Medical Research*—a journal which has now almost reached the stage at which it might be sub-divided into three journals, one dealing with medical entomology, a second with malaria and paludism, and a third with other subjects including kala-azar.

Mosquitoes.—The first place must undoubtedly be given to Mr. P. J. Barraud's revision of the culicine mosquitoes in India, a very fine and monumental work, parts xix to xxii of which have appeared in the *Indian Journal of Medical Research*. A second important publication of the year is Dr. C. Strickland's illustrated *Key to the Identification of the Anopheline Larvæ of India, Ceylon, and Malaya*, with a foreword by Sir Ronald Ross previously referred to.

An exceedingly important contribution to the whole question of the bionomics of mosquitoes of genus *Anopheles* is one by Dr. K. B. Williamson of Singapore in the *Malayan Medical Journal*. This line of work is so new, and so important that, although the paper refers to Malayan rather than Indian conditions, we feel that we cannot do better than quote Col. Alcock's review of it in the *Tropical Diseases Bulletin*.

"Although a good deal of the information contained in this valuable report is of only local interest," he writes, "it contains numerous items of general interest, particularly in its experimental investigation of the surmise first expressed by Sir Malcolm Watson that the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

fitness of a potential breeding-place for Anopheles is determined by the composition of the water." One of the most general conclusions is that "all observations point to the almost complete cessation of anopheline breeding [in growing rice fields] when the acidity of the water falls to pH 6, and a sharp decrease below pH 6·4," although it is emphasized that on one occasion larvae of rice-field species were found in abundance in a drain (between rice-fields) where the water varied from pH 5·3 to 5.6. Another general conclusion from comparisons between certain dissimilar waters sterile to Anopheles *in situ* and the same waters made fertile to Anopheles in the laboratory, is that the natural sterility of waters may be due to their deficiency in food-stuffs. These experiments were made by introducing small floating cages of bamboo and muslin into the natural waters that were free from Anopheles breeding, the cages containing some of them well-grown Anopheles larvæ and some of them Anopheles eggs, in measured numbers; the results of the observations are compared with the results of laboratory experiments where larvæ and eggs were placed in water from the same natural sources in some cases without food, in other cases with a suitable supply of food. The results of the ingenious experiments here described justify the conclusion—probably of general import, but at least for the particular waters examined and the particular species of Anopheles made use of for experiment—that the food-factor is the determining one.

Experiments and observations are recorded respecting the larvicidal powers of common aquatic (paddy-field) bugs and of common paddy-field fishes. Among bugs the Belostomidæ were found most efficient. Among fishes an Ophiocephalus, the species of which are not usually credited with eating anopheline larvæ, were voracious enough in the laboratory, though not equal to the well known Osphromenus.

The flora associated with areas in Perak where the amount of Anopheles breeding is known receives notice. The presence of a Utricularia (*U. flexuosa*) "appears to characterize either the limitation of anopheline species to *A. sinensis* and *barbirostris* or the complete, or nearly complete, absence of all anopheline breeding."

The larvicidal properties of roasted *amang*—a ferruginous residue from a local mine—are described as sufficient to justify its practical probation. Rubber oil is also noticed as an efficacious larvicide, either alone or as an adjuvant to other oils.

The statement is made that algæ form only a small portion of the food of Anopheles larvæ, the bulk of their food being "of an amorphous character and of obscure origin"; [but this generalization must depend on very much limited observations—perhaps on observations of larvæ from rice-fields at some particular time.]

A further series of papers with reference to mosquitoes published during the year are chiefly of technical interest, and may be referred to more briefly. Majors J. A. Sinton and G. Covell deal with the relationship of the morphology of the buccal cavity to the classification of anopheline mosquitoes. B. S. Chalam deals with the relationship of the blood meal of the female *Anopheles* and of other factors to the fertilisation of its ova, with the resistance of *Anopheles* ova to desiccation, showing that the ova of *A. subpictus* and *A. stephensi* are still viable after desiccation for 12 days. Dr. Strickland deals with hypomelanism in an anopheline, apparently *A. vagus* with unusual markings.

The history of *Anopheles ramsayi* (*vel. pseudo-jamesi*) is a very difficult subject. This new species of *Anopheles* was first discovered, as far as we can make out, in Assam by Dr. G. C. Ramsay, who sent his material for study to Major Covell at the Central Malaria Bureau, Delhi. Major Covell's full and very detailed report of this new species was published in the *Indian Journal of Medical Research* for April, 1927, p. 1019. (The date of issue of this number from the press, we are informed by the publishers was the 17th May, 1927.) In the meantime Dr. Strickland had discovered what is apparently the same new species in Bengal, and his and Dr. Chowdhury's (incomplete) description of the new species was published in the *Indian Medical Gazette* for May, 1927, p. 240, the editors of this journal being at the time in complete ignorance of Dr. Ramsay's and Major Covell's work on what is apparently the same species. (The May 1927 issue of the *Indian Medical Gazette*, we are informed by the publishers, was published on the 10th May, 1927.) Which name therefore takes priority, we must leave it to the experts to decide. Subsequently this new species has been shown to be a carrier of malaria, though perhaps not a very important carrier. A paper dealing with the same species was published in the *Indian Journal of Medical Research* by Mr. I. M. Puri, M SC., PH.D., F.E.S., in the October issue. He concludes that *A. ramsayi* and *A. pseudo-jamesi* are one and the same new species, and that the larval characters of the two are identical.

Sandflies have continued to attract attention during the year, especially now that they are known to be of importance with reference to the transmission of *Leishmania* infections. Major J. A. Sinton continues his studies of Indian sandflies in the April and July issues of the *Indian Journal of Medical Research;* he gives a new description of *Phlebotomus malbaricus;* further records of the geographical distribution of different species; "miscellaneous notes" which include some very interesting points with reference to the leishmania transmission problem; discusses the value of the female genitalia in the identification of species; also the morphology of the buccal cavity in different species; and describes a new species caught in Lahore, *Phlebotomus christophersi.* Workers on *Leishmania* infections will be under a very great debt of gratitude to Major Sinton for the tremendous amount of valuable work which he has put into the clearing up and extension of our knowledge of these insects and for his notes with regard to the classification and identification of species; it is a field which he has made particularly his own. His demonstration of the chief Indian species at a meeting of the Royal Society of Tropical Medicine and Hygiene will further help to broadcast knowledge with regard to the genus in general.

Lieut.-Col. T. C. McCombie Young discusses the sandflies of Bombay city, on which he has been working. Three species are present: *P. papatasi, P. argentipes,* and *P. minutus*—together with its variety *niger.* The presence of the first named species is curious in view of the freedom of Bombay from endemic kala-azar, but the author is by no means satisfied that conditions in Bombay city are unfavourable for the spread of the disease; it may still appear there. Together with Capt. B. S. Chalam, he describes two new species from Bombay, *P. chalami* and *P. colabænsis.*

Miscellaneous.—A. B. de Castro in our issue for May records notes on four cases of bee sting—an article with perhaps nothing very new in it, but of interest from its clinical descriptions. Mr. Barraud has published a note on rat fleas collected in Assam. A curious feature of this collection of 213 Assam fleas is the very high prevalence of *Xenopsylla cheopis;* every single rat flea from Shillong with one exception—i.e., 61 out of 62—were *X. cheopis* and not *X. astia;* yet plague is entirely absent from Assam. A most extraordinary case, literally one of "sweating blood," is described by Lieut.-Col. R. Kelsall, in our issue for October; the patient, a Mahomedan lady in Rangoon, was accustomed to keep chickens in intimate contact with her and to carry them in her clothing at her breast. The fowl fleas, *Echidnophaga gallinacea,* had passed from the chickens to her skin, had bitten her, and caused the tiny petechial lesions on her chest.

In the treatment of myiasis, an affection which only too frequently comes to infect ulcers, nasal sores, etc., in India, M. M. Dave advises the local application after cleansing, on a cotton-wool plug of a solution of one drachm each of chloroform, carbolic acid, creasote, and oleum terebinthinæ. Cases are especially frequent during the rainy season.

MEDICAL PROTOZOOLOGY.

An event of the year, perhaps, is the publication of Knowles' *Introduction to Medical Protozoology* (actually published in December, 1927, although labelled 1928 on the title page by the publishers). Whilst this book is intended primarily as a textbook for students at the Calcutta School of Tropical Medicine, the author hopes that the book will have a much wider value and that it will be of value to laboratory workers throughout the tropics, and especially to the laboratory worker who is isolated and out of touch with the large libraries. It has been reviewed in our columns for March 1928 by Colonel Mackie. The book must stand or fall by its own merits; it is for others to judge whether it is of any use or none.

Major H. E. Shortt publishes a note on cytoplasmic counter-staining in protozoological technique and recommends that, after staining by, e.g., Heidenhain's iron-hæmatoxylin method, the slide should be passed up through the graded alcohols to absolute alcohol, then immersed for a few seconds in light green (not S. F.), or brilliant green dissolved in a carbol-xylol mixture. The reviewer has tried this method and finds it of great value in giving contrast to the staining.

Major Shortt with C. S. Swaminath describes the life history of *Monocystis mackiei n.sp.* parasitic in the sandfly *Phlebotomus argentipes*. This is a new natural gregarine parasite of sandflies, of importance to workers with this genus of insect in connection with the transmission of *Leishmania* infections. The paper is illustrated with a magnificent series of photomicrographs, the originals of which were shown at the F. E. A. T. M. Congress in Calcutta in December, and which aroused the enthusiasm of many of our foreign visitors.

A. Vasudevan in the *Indian Journal of Medical Research* for July describes a most interesting case of *Sarcocystis* infection of man. The pectoral muscles were affected and the infection had given rise to an irregular ulcer about 2¼ by 1½ inches in diameter on the front of the chest. The memoir is illustrated by excellent coloured drawings of the lesions and photomicrographs.

Assistant Surgeon B. M. Das Gupta, describes a *Trichomonas* found in the gut of a non-poisonous colubrine snake (*Ablabes calamaria*); the parasite was readily cultured in Row's hæmoglobin saline medium and appears to differ from the previously described trichomonads of snakes in possessing four, instead of three, anterior flagella.

M. A. Narayan Rao has a valuable memoir on *Piroplasma gibsoni*. First described as a natural piroplasm of jackals, he now claims that it may also infect dogs, either naturally or experimentally. A detailed account of its life-history in the vertebrate host is given, together with photomicrographs, and schizogony forms are described from the spleen. The infection is more acute in type in the dog than in the jackal.

TROPICAL DERMATOLOGY.

A special feature of the year has been the series of papers contributed from Col. Acton's skin clinic at the Calcutta School of Tropical Medicine. These have been twofold in character; a series of clinical papers on the more important and common skin diseases of the tropics contributed to this journal, and a second series on the rarer types of tropical skin diseases contributed to the *Indian Journal of Medical Research*. It is hoped that on the conclusion of these series of publications Colonel Acton will be in a position to publish two books; a textbook on the commoner skin diseases of the tropics for the use of the general practitioner in India and the tropics; and a large atlas of tropical skin diseases for the more advanced worker. The colour plates for the latter, thanks to the invaluable work of Mr. H. M. Roy—Colonel Acton's special artist at the School—are already available, and constitute what is almost certainly an absolutely unique collection. The number of patients seen in this clinic has increased in seven years from 300 a year to over 3,500 a year.

Of the more general and popular papers, the first place must be given to the paper in our issue for August, 1927, by Lieut.-Col. H. W. Acton and C. McGuire on *Tinea cruris* infection. This is summarised as follows in the *Tropical Diseases' Bulletin*.

A well illustrated communication containing a useful detailed account of the disease as seen in India. Difficulty in diagnosis would seem to depend upon the frequent secondary pyogenic infection and the trouble involved in the detection of the fungus, preparations in 40 per cent. potash often requiring 24 hours' clearing for its definition. Infection occurs where the epidermis is thinnest, especially the cleft between the 4th and 5th toes. The conditions necessary for infection relate to moisture, warmth and friction. Children do not usually suffer. The nails of the fingers are more commonly affected than those of the toes, probably as a result of scratching. "*Tinea cruris* never extends above the neck on to the face although it may attack any other part of the body." A secondary streptococcal infection is the commonest complication. This may occasionally lead to a cellulitis or sometimes to a generalized condition with the appearance of an exfoliative dermatitis. These cases are frequently a mixture of streptococcal infection and arsenical dermatitis following treatment for supposed syphilis. Secondary staphylococcal infection is frequent, while among Indians secondary contamination with *B. tuberculosis* may give rise to warty lesions.

In describing the cultural characterstics of the Epidermophyton, it is asserted that the colour variations of the cultures are due to substances in the media and not to varieties of species. Treatment in the acute stages with secondary infection and bullous or vesicular lesions consists in the frequent application of calamine lotion (allowed to evaporate) during the day and a 1-2 per cent. mercurial ointment at night. For those cases showing a marked staphylococcal infection acriflavine solution 1 : 1000 is recommended. As soon as the lesions are dry, Whitfield's ointment is advised. In mango toe, with great thickening of the skin in the interdigital clefts, the affected area may be painted with Resorcin 1 drachm in Tr. Benzoin Co. 1 oz. This is to be applied at night, but requires careful observation and control. Chronic cases, which do not react to ointments, etc., are benefited by X-rays, both filtered and unfiltered, frequently in fractional doses. To prevent infection or reinfection after cure a sulphur camphor dusting powder is recommended for application to the feet and groin on alternate days with a simple absorbent powder, for the purpose of keeping these regions dry.

A second paper from the same clinic is the one by Lieut.-Col. Acton and G. Panja in our issue for November on seborrhœic dermatitis. This condition is due to infection with the *Malassezia ovale*, or "bottle bacillus of Unna." Three types are recognised: pityriasis capitis, which starts on the scalp and spreads to the body; pityriasis versicolor, which starts on the chest and spreads upwards to the neck and face; and pityriasis flava, which starts on the face and neck and extends down to the chest. Secondary streptococcal infection of the lesions may lead to an acute eczematous condition. The invasion of the skin is predisposed to by overactivity of the sebaceous glands. The invasion may extend to the face (comedo and acne) or in children to the body (flannel rash). In adult life the hair follicles of the scalp may be invaded, causing alopecia (baldness). In infancy the most characteristic lesion is miliary sebaceous acne; at puberty acne and kerosis, in which latter condition the skin is greasy and thickened with widely patent mouths of the sebaceous glands; in adult life infections of the body are common; and later in life baldness and seborrhœic warts. The acne bacillus is not the true cause of acne, but a secondary invader. The authors have been the first to successfully cultivate *Malassezia ovale* in vitro; washed scales from the dandruff areas are placed on the upper part of a tube of Petroff's glycerinated egg medium, and here, as the two conditions essential for the growth of the fungus are oiliness and dryness, the mycelium

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

grows on the surface of the medium. Subcultures are more easily obtained than primary ones. The chief difficulty in diagnosis is the secondary infections, and it is often not realised that these cases are due primarily to infection with a fungus, and that unless this underlying fungus infection is dealt with the disease will recur.

By way of treatment, that of the scalp must be continuous. In young children the greasy scales should be softened with warm olive oil overnight, a ½ per cent. mercury oleate being a good application. In the morning the oily application should be washed out with soap and water and a resorcin lotion applied. In impetigo an ointment with 5 to 10 grains of hydrarg. ammoniata to the oz. is useful. For eczema rubra on the body calamine lotion should be applied until the acute inflammation subsides, followed afterwards by resorcin ointment, 5 to 15 grains to the oz. In pityriasis capitis of later life, with baldness coming on, a soap spirit lotion should be well rubbed into the scalp each night and then thoroughly removed with hot water and soap. The application of an ointment at night containing 10 to 30 grains each of sulphur and camphor to the oz. is helpful, the ointment being washed out again in the morning, or a sulphur lotion applied. Resorcin is the next best remedy to sulphur, and cresol and hydrarg. perchloride may be used in the form of a lotion. In cases of acne the blackheads should be expressed, a sulphur-camphor lotion used at night, and a bland face powder during the day. Boils should *not* be fomented, as this tends to produce fresh crops of them; an evaporating or calamine lotion is better. Many boils become spontaneously absorbed if left alone; but if they mature incision should be made with a very fine knife such as a cataract knife, the contents thoroughly expressed, and the point touched with tincture of iodine. For seborrhœa of the body resorcin, an ointment containing from 10 to 30 grains, at night, with a dusting powder containing sulphur during the daytime is best. Starches and fats must be cut down in the diet, and some cases may require X-ray exposures.

Col. Acton and Dr. L. E. Napier deal with post-kala-azar dermal leishmaniasis, the "dermal leishmanoid" of Brahmachari, giving a report based on 44 cases seen. In almost all cases this follows after cure of kala-azar, but occasionally occurs in a patient who lives in a kala-azar area, but has not had kala-azar. The parasite is almost certainly *Leishmania donovani*, and corresponds in all respects to the parasite of kala-azar. The condition begins with the appearance, especially on the face and extensor surfaces of the forearms of very tiny leucodermic spots, which may later appear all over the body. At each of these spots a tiny granulomatous nodule next develops, until finally the clinical appearance of the patient may closely simulate nodular leprosy; in some cases the granulomatous lesions are localised but large, and may infiltrate mucous membranes, the condition closely simulating xanthoma tuberosum. Leishmania can usually be readily demonstrated in films from the nodules; or in the early leucodermic stage by culture. The patient is in robust health and has no visceral leishmania infection. The tendency is apparently towards spontaneous cure after a number of years, and the best line of treatment is injections of pentavalent antimony salts.

In the *Indian Journal of Medical Research*, Col. Acton deals with porokeratosis, giving an account of eight cases seen. This rare disease is a form of hyperkeratosis. It is apt to occur on the hands, feet, and arms. The lesion is a raised one resembling a corn, which as it grows presents an irregular raised wall surrounding an atrophic depressed centre. A familial tendency and a lowered basal metabolic rate are present. Porokeratosis in fact is a localised keratosis which falls into the group of skin diseases—xeroderma, scleroderma, follicularis, morphœa, etc.—which are associated with hypofunction of the thyroid. The most successful line of treatment is to put the patient to bed, give him an intensive course of desiccated thyroid extract—2 grains twice a day or so, and have the pulse counted every four hours. Sufficient thyroid is given to keep the pulse rate at from 90 to 100 per minute. Within a few days very marked improvement is noted, and usually cure results within a fortnight.

A further splendidly illustrated paper by Col. Acton is one on sarcoids. The name sarcoid is unfortunate, as these vascular tumours have nothing to do with sarcoma; they are angiomatous growths which are innocent in character. There are four types: (*a*) small superficial venous angiomata—the "tach de Morgan"; (*b*) nodular types which are due to angioma formation in the sub-capillary plexuses of the skin. These often form small tumours which may be the size of a walnut and bleed readily. More than 20 such cases have been seen in persons convalescent from epidemic dropsy. Occasionally, instead of this angiomatous change being localised, it is diffuse and produces dark red extensive plaques which may occur on the back of the hands, the face, or the thigh; (*c*) the subcutaneous sarcoid, where the angiomatous lesions are situated more deeply in the subcutaneous tissue, and where diagnosis may only be possible by excision and section cutting; and finally, (*d*) sarcoids of the extremities simulating erythema induratum. Sarcoids are acquired as the result of the irritation of vessels in the different skin layers from toxins absorbed from the gut, which cause increased permeability of the vessel walls, œdema, and angiomatous overgrowth. Diagnosis depends on being familiar with the condition. The localised lesions are best treated by carbon dioxide snow, but the septic focus should always be looked for and treated.

On other interesting "skin" cases, we may mention M. Umar's interesting and very extensive case of dermatolysis in our April issue; D. J. Asana's case of von Recklinghausen's disease, with its admirable photographs, in our November issue; and Dr. Burke's interesting case of giant urticaria with marked periodicity in the symptoms in our February issue.

BIOCHEMISTRY.

Several of the papers already commented on might perhaps have been considered rather in this section. Of strictly biochemical papers, Dr. J. P. Bose deals with the chemistry of the blood in normal healthy Indians and its variations in disease in our issue for July. A table is given showing the minimum, maximum, and average values of the different constituents in health, and there is a useful discussion on the variations present in the different elements in different diseases. This paper is in itself so much of a summary that an abstract of it is impossible.

Major C. H. H. Harold, O.B.E., R.A.M.C., deals with the eu- and pseudo-globulins, with special reference to the Wassermann test (*R. A. M. C. Journal*, February, p. 92). From the Haffkine Institute, Parel, Colonel Mackie reports that Major Sokhey has been studying the normal basal metabolic rate for Indians, using Collin's modification of Tissot's gasometer. The 25 subjects studied so far show an average rate of 15 per cent. lower than the accepted rate for Europeans. Work on these lines is proceeding.

MEDICO-LEGAL.

The most interesting paper of the year is Major J. C. De's medico-legal study of the Calcutta riots of 1926; an article which has aroused a great deal of interest, and which was reprinted verbatim by the *Statesman*. The different types of injuries concerned in different systems of the body are well described, and any civil surgeon who has to give evidence with regard to injury cases in the courts would do well to study the article closely, for its medico-legal lessons are important. In one case, for example, the statement of witnesses that a European police sergeant had shot a rioter with his revolver was disproved by the finding of buckshot in the wound; the truth was that the rioter was attacking the police sergeant with a spear when he was shot by a police constable armed with a shot-gun. In a second instance an exceedingly trivial wound—to all appearance a stab wound behind the mastoid process—had

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

caused fatal hæmorrhage from the vertebral artery into the ventricles of the brain, the occipito-atlantoid ligament having also been wounded. A third curious instance cited is one in which a passing taxi driver jumped off his taxi, cut the throat of a victim who was already probably dead from *lathi* injuries to the skull, remounted his taxi and drove off. This story, as related by witnesses, was confirmed by the exceedingly slight extent of the bleeding from the wound in the neck. If the riots of 1926 in Calcutta have done nothing else, they have added considerably to our knowledge of the types of injury to be expected in such circumstances.

The question of counterfeit drugs was dealt with in our editorial for September. The position in India is exceedingly difficult. As the law at present stands, apparently, reputable firms have no remedy against pirates other than to sue them in court—a lengthy and expensive business. Apparently anyone can copy a registered label—or, for that matter, take the label of a well-recognised firm off a used-up bottle of their products and paste it on to a bottle of any rubbish of his own composition and sell the product as that of the first class firm concerned. The police apparently have no power of search and seizure, such as exists in Great Britain and the United States. From every point of view an all-India Food and Drugs Act seems to be called for, but the difficulties of enforcing its provisions will be obvious.

An interesting case of poisoning by the seeds of the yellow oleander (*Cerebra thevetia*) is recorded in our issue for August by B. M. Roy. There was marked heart-block and coma, and the patient's life was apparently saved by the prompt and vigorous measures instituted, especially the washing out of the stomach.

LABORATORY METHODS, SERA, VACCINES, TECHNIQUE.

A useful article is that by Lieut. J. F. Osman Bodman in our December number on the more easily observed pathological changes in the cerebrospinal fluid, and their clinical interpretations. This article it is impossible to summarise, but it shows how much information can be derived from a simple naked eye observation of the fluid and from a simple opacity test for its total protein content. It should be consulted in the original.

Capt. S. D. S. Greval deals with the effect of excess of the hæmolytic amboceptor on the minimum hæmolytic dose of complement in the Wassermann reaction. He concludes that a hæmolytic system of guinea-pig complement, sheep red cells, and antisheep hæmolytic amboceptor leaves nothing to be desired. An excess of hæmolytic amboceptor, using 10 M.H.D. instead of 5 M.H.D., does not affect the M.H.D. of the complement. A false negative reaction does not result from an excess of the hæmolytic amboceptor.

Lieut.-Col. J. Cunningham, describes a simple method of handling squirrels and other small animals for bleeding and other purposes. A box, forceps, and muzzle are described, by the use of which squirrels or other small biting animals can be held for bleeding and other purposes with perfect safety to the attendant. The squirrel, as he points out, is a most useful animal for laboratory purposes. It is hardy, lives well in captivity, is easily fed, and is not expensive. (*Indian Journal of Medical Research*, July, p. 81).

Assistant Surgeon J. H. Theodore, I.M.D., describes a special enrichment medium for the growth of the gonococcus, using a serum agar made with human placental broth. The growths obtained are very luxuriant, whilst human placenta is usually readily obtained by medical men, and the method should be more widely known (*I. M. G.*, August, p. 444).

Capt. C. P. V. Shunker advocates counter-staining with picric acid in the examination of sputum for tubercle bacilli. The film is stained in the usual way with hot carbol-fushin, washed, decolourised with 25 per cent. sulphuric acid, treated with absolute alcohol, again washed, and then counter-stained with a half saturated watery solution of picric acid for 5 to 10 minutes. The red tubercle bacilli show up better against a yellow background than against the usual blue background obtained by counter-staining with methylene blue. (*I. M. G.*, February, p. 84).

From the Central Research Institute, Kasauli, Capt. K. R. K. Iyengar sends us the following interesting résumé of the work by Lieut.-Col. W. F. Harvey, C.I.E., I.M.S. (retd.) and himself on the development, duration, and restoration of immunity in vaccine therapy.

Much of the literature on the subject has centred around determinations of agglutinin increase or decrease. Our observations therefore of agglutinin production and protection simultaneously evaluated will be of considerable interest in this connection.

The organism which we worked with, as in most of our work on immunity problems (*Indian Journal of Medical Research*, 1921–23), is *B. avisepticus*, chosen because of its pathogenicity to pigeons. This organism has the additional advantage that, as a member of the hæmorrhagic septicæmic group of organisms it is related to *B. pestis*. The pigeon has been chosen as the test animal because of its relative cheapness and therefore availability in numbers which would carry weight not only experimentally but also statistically. We have preferred to rely on experiment based not so much on minimum lethal dose but on what we call a "minimum lethal picture" in which the minimum lethal dose and the multiples of the dose are all represented. In every testing experiment done, there was introduced a complete series of control animals, which ensured that we had always at hand the equivalent of what, statistically, could be described as an alternate series for comparison.

In this experiment 600 pigeons received inoculation and then served at stated intervals for the test of protection. When the duration of protection had come to an end, the pigeons left over were used for the restoration and duration of immunity after re-inoculation. The usual method of re-immunization is to repeat the original immunizing dose. In the present investigation we have sought to determine the conditions under which immunity can be completely restored especially in regard to size of re-immunizing dose. This is a most important matter, for it is well known how difficult it is to get large bodies of men voluntarily to undergo prophylactic inoculation and how very much more difficult it is to get them to repeat their previous experience by consenting to re-inoculation. We experimented with a series of doses for re-immunization—the original optimum minimal prophylactic dose and doses which were ¼, ⅛, 1|16 and 1|32 of this.

Conclusions.

(1) Single doses of vaccine can produce immunity, but not of so high degree as two or three doses.

(2) Some immunity can be obtained within a week of commencement of inoculation.

(3) Full immunity is attained within three weeks of the commencement of inoculation.

(4) The duration of immunity after inoculation is shorter than is generally appreciated.

(5) The agglutination titre curve was not parallel to the immunity or protection curve. There is a marked diminution of agglutinins while protection is still maintained at its maximum.

(6) Re-immunization may be carried out with doses which are smaller than even the smallest dose originally required to confer maximum immunity. Animals receiving ¼th and ⅛th of the original dose showed as high a degree of immunity as those receiving the full dose. The immunity so conferred, is as great and lasts as long as, but no longer than, the original immunity.

SERVICE NOTES.

Once again we are indebted to Col. J. K. S. Fleming, Deputy-Director-General, I.M.S., for a review of the year. The following is his report.

(1) It is understood that the Secretary of State's sanction to the reconstitution of the Indian Medical

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Service referred to in the Service Notes of 1925 and 1926, has been received, and the question of giving effect to the proposals is now receiving the attention of the Government of India.

(2) Reference paragraph 2 of the Service Notes forwarded in December, 1926, regarding passage concessions to Indian Officers of the Indian Medical Service, the Secretary of State has decided that all officers appointed in India to the Indian Medical Service are to be deputed to England to take the Junior Royal Army Medical Corps Course within the first year of their service. All officers of the Indian Medical Service including those of Asiatic domicile will also be required before promotion to the rank of Major, and between the 7th and 10th year of their service, to complete the Senior Officers' Course at the Royal Army Medical College, Millbank. Attendance at both these courses will be regarded as duty. The concessions that have been sanctioned under the above-mentioned scheme are:—

(*a*) Free return passage when taking the Junior Royal Army Medical Corps Course in the case of all Indian Medical Service Officers appointed in India.

(*b*) Free return passage and full pay when taking the Senior Officers' Course at the Royal Army Medical College, Millbank, in the case of all Indian Medical Service Officers, whether of Asiatic or non-Asiatic domicile; also travelling allowance from their headquarters to the port of Embarkation and *vice versa*.

(*c*) Free passage to India for Indian Indian Medical Service Officers granted study leave on conclusion of the Senior Officers' Course.

(*d*) Free return passage for Indian Indian Medical Service Officers granted study leave, who are ineligible for the Senior Officers' Course or who are refused study leave on the conclusion of that course.

Pending the introduction of the above scheme in full the Government of India in Army Instruction India B. 136 of 1927 have decided that an officer of the Indian Medical Service of Asiatic domicile, whether in Military or Civil employ, who has already attained the rank of Major or who is likely to attain that rank before the full scheme is brought into force will be allowed one free return passage to the United Kingdom when granted study leave.

(3) The 7th Congress of the Far Eastern Association of Tropical Medicine was held in Calcutta, between the 5th and 12th December, 1927.

(4) The question of establishing a General Medical Council in India is, at present, receiving the attention of the Government of India and pending the formation of this Council a proposal of appointing a Commissioner of Medical Education, is it is understood, under consideration.

(5) Under Army Instruction India No. B. 155 dated 12th July, 1927, revised rates of furlough pay in India for Indian Medical Service Officers holding military administrative appointments were sanctioned:—

"With effect from the 1st July, 1927, officers of the Indian Medical Service holding military administrative appointments, while on leave in India, other than privilege leave, will receive pay at the following monthly rates, to which full overseas pay will be added if admissible."

	Rs.
Director of Medical Services in India ..	2,400
Deputy Directors of Medical Services, Commands	2,060
Deputy Director of Medical Services, Army Headquarters	1,875
Directors, Army Headquarters. Assistant Directors of Medical Services, Districts and Independent Brigades .. Consulting Dermatologist of over 25 years service.	1,800
Consulting Dermatologist of 25 years or less service	1,650
Assistant Director Medical Services, Army Headquarters	1,610

(6) Under Army Instruction India No. B. 159, dated the 19th July, 1927, the tenure of administrative appointments assigned to Colonels and Major-Generals of the Indian Medical Service will count from the date of promotion to such rank but the pay of such appointments will not be admitted until the duties have been actually assumed. When an officer on leave in the United Kingdom is promoted he must return at once to duty unless granted special permission to the contrary.

The above change is to be applied only to such officers of the Indian Medical Service as are promoted to administrative rank on or after the date of this instruction.

(7) In accordance with the Royal Warrant dated 10th June, 1927, General Officers are to be placed on the Retired List at the age of 60 instead of as heretofore at the age of 57. The provision for a General Officer, affected by age limit, to continue in employment for not more than one year in any special case has been cancelled.

(8) Under Army Instruction India No. B. 135, dated the 14th June, 1927, an officer of the Indian Medical Service commissioned on or after 1st July, 1926, who has held a resident appointment of not less than one year in a recognised civil hospital in the United Kingdom or in India may be granted an antedate not exceeding one year in respect of the period spent in such an appointment provided that the interval between the termination of the hospital appointment and the date of entry into the service shall not ordinarily exceed six months. This antedate will count as commissioned service for the purpose of increments of pay, promotion, retirement and retired pay, but not for gratuity.

(9) The Government of India have in consultation with the Secretary of State considered the question of requiring Indian Medical Service Officers retiring on gratuity to join a reserve. In accordance with the proposals which have been sanctioned officers appointed to the Indian Medical Service on any special terms similar to those of July 1926, will, if they retire on gratuity after 12 years service or over, be liable to recall to military duty in an emergency up to the age of 55. The question of enforcing the liability to recall in the case of officers retiring on gratuity after less than 12 years' service has been reserved for consideration when the effect on recruitment of the impending reorganization of the Indian Medical Service is known.

(10) The Government of India have accepted the position that an administrative medical officer in civil employ should not be compelled to retire on the completion of his tenure of appointment if within the age limit, and that he can avail himself of any leave admissible to him up to the date on which he becomes superannuated. During such leave he will no longer retain a lien on his administrative post but on some other post such as a civil surgeoncy in the province in which he was employed prior to his appointment to an administrative post and the officiating incumbent will be permanently appointed from date of vacancy.

(11) Since the beginning of 1927, twenty European officers have been admitted into the Service in accordance with the Special Recruitment terms of 1926 which were detailed in the Service notes forwarded in December, 1926. These terms may, however, be repeated again:—

A gratuity of £1,000 after six years service or £2,500 after twelve years service together with free return passage to any officer so appointed who no longer desires to remain in the Service subject to 12 months notice of his intention being given.

Two Indian candidates were appointed early in the year. A Selection Board was held in Simla in August of this year for the recruitment of further Indian candidates to the Service. Twenty candidates were selected and recommended to the Secretary of State for permanent commissions and sanction to the appointment of the first eight on the list has just been received. The Secretary of State's orders regarding the remaining 12 candidates selected are awaited.

* * * * * *

The reviewer cannot conclude this report of the year without again thanking those who have contributed to it. He trusts that, with regard to similar future annual reviews, he may have the assistance of still further contributors; there have been fifteen in all to this present one, but there may be those whom, through inadvertence, he has not written to, but who would be willing to contribute. If so, their reports would be very welcome. Directors of Public Health and of large medical research institutes are, one knows, very busy men, but a *brief* review of the year's work is always very welcome, and perhaps of special value in giving our readers an up-to-date and bird's-eye view of the present position of medical and public health work in India.

NEURASTHENIA IN THE TROPICS.*

By HUGH W. ACTON,

MAJOR, I.M.S.,

Professor of Bacteriology, Pathology and Helminthology, School of Tropical Medicine and Hygiene, Calcutta.

THE word "neurasthenia" means nerve debility, and is characterised by a general feeling of ill health, which in turn is associated with introspectiveness, and a morbid dread that some disease is developing or will develop at a future date. The patient in helplessness seeks medical aid, and in his anxiety that nothing should be missed in his case spends hours in introspectively collecting information about himself. He generally presents the physician with a history of his case in four or more pages of close written foolscap detailing the symptoms he has suffered from year after year, month by month, or day by day. The term neurasthenia conveys to the lay public the idea that the source and origin of the disease is due to a debilitated state of the nerves, but without obvious cause. In fact there is the stigma associated with the disease that a certain amount of the symptoms are put on in order to elicit sympathy, or escape work; in other words that the patient is not as bad as he thinks. The opinion of some medical men seems to bear out this accepted view of the lay public, for no attempt is made to find out why these nerves are in this depressed or excitable state. The patient is generally told that his symptoms are all due to nerves; not to worry, but to have made up a prescription containing some beastly tasting medicine like valerian or asafœtida, along with bromides which further depress the nerves. Often in vain the patient cannot obtain relief by medical treatment, so he hearkens to the appeals made to him by the many quack advertisements that appear in the papers that guarantee a cure for his various symptoms. The dread of loss of virility that develops in many of the male patients is fostered by advertisements falsely describing the nature and cure of spermatorrhœa.

In this paper I will endeavour to point out that neurasthenia *is real ill health* associated with certain existing causes, and not merely a feeling of ill health. In the tropics there is a further association with certain predisposing causes that are more commonly present than in temperate climates. It is obvious that before we can obtain a cure we must first deal with any exciting causes, then remove the predisposing causes, and aid the different endocrine glands that are not functioning properly; it is not until then that we can hope to get a real and permanent cure. It is little use trying to quiet the nerves with bromides, or to aid the functions of the endocrine glands by shot-gun prescriptions of the various endocrine products now on the market, before removing the exciting cause.

The causation.—The exciting cause is due to a depression of the function of certain endocrine glands, mainly that of the thyroid, and to a less extent of the adrenal glands. The functions of these glands may be depressed in two ways:—

(1) By the direct action of the toxins of many of the acute diseases that are common in the tropics, for example, enteric fevers, cholera, plague, Shiga's dysentery, smallpox and blackwater fever. These acute diseases, when severe, leave for a long time their after-effects on these two glands. More rarely the depression of function is due to a slow poisoning by chronic diseases such as malaria, syphilis, hookworm infection, etc. In women we have also to consider the question of septic diseases of the genito-urinary tract.

(2) The most fertile cause is an interference with the digestive functions which is brought about partly as the result of toxins, and partly by putrefactive changes in the gut. Such diseases as pyorrhœa often set up a gastritis which in turn may be associated with gastric or duodenal ulcer. They invariably produce profound changes in the digestive processes that take place in the gut. The commonest cause after pyorrhœa is that due to chronic dysentery, both the amœbic and bacillary type. In such cases, when the stool is plated, instead of getting the typical colonies of lactose fermenters belonging to the coliform group, we find a large number of opaque non-lactose fermenters, streptococci, and sometimes yeasts. The alteration of the whole of the intestinal flora must play an important part in this slow process of poisoning (toxæmia), for it means that the body has to deal with a totally different group of end-products of these new bacteria, that now inhabit the intestine.

The predisposing causes.—The predisposing causes are much more numerous in the tropics than in temperate climates, for these reasons:—

(1) There is a greater tax on the body as the result of the continued high atmospheric temperature and the excess of humidity, for the skin continually requires a large quantity of blood to keep up the continual perspiration, in order to keep the body temperature lower than that of the atmosphere. Eastern races recognise this, and therefore rarely eat a meal during the heat of the day. The two main meals are taken first thing in the morning and towards evening. To add to these difficulties of retaining the body temperature at normal, i.e., 98.4°F., European dress (particularly amongst men) is totally unsuited for the tropics. Starch collars, three or four layers of clothing covering the body such as the coat, waist-coat and shirt do not help the rapid evaporation of the sweat. The long nightgown

* Being a paper read before the Medical Section of the Asiatic Society of Bengal on Monday, the 22nd November, 1926.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the Arab may not be becoming, but is very comfortable and cool.

(2) The tendency to the production of anæmia that occurs by lack of ventilation during the hot weather. In the day time to keep the rooms cool the doors and windows have to be locked up, and the only circulation of air is by the fan churning it round and round without replacement. Sleeping under a mosquito net at night time is another fruitful source of living in an atmosphere charged with an excessive amount of carbon dioxide. Both these defects in our present methods of living could be corrected by the use of thermantidotes during the day, or better still a cool room such as we have at the Calcutta School of Tropical Medicine, and the use of proper electric fans at night in order to keep off mosquitoes. A low mosquito net 2½ to 3 feet high round the four sides of the bed and open at the top would protect the hands and feet from their bites, and would allow free access of air.

(3) The poor quality of the food during the hot weather. For at least seven months in the year, the quality of the meat is distinctly poor in the markets. In the *mofussil* conditions are still worse, for these people rarely get any meat other than fowl. In fact in the *mofussil* one lives on the chicken before it is born—i.e., as an egg, and starts cooking it before the flesh has got cold or has hardly had time to die. Only during the winter months does the quality of the beef and mutton improve, and then there is also a great variety of game in the larger markets. During the hot weather vegetables likewise are difficult to procure and of a poor quality.

(4) The inadaptability of the Indian cook to European methods of cooking. Amongst Indians it is the custom to eat highly spiced curries and similar dishes cooked with a large amount of capsicum, which is very irritating to the stomach for those who are unaccustomed to these hot spiced dishes. To add insult to injury these curries are generally cooked in mustard oil which contains the irritative allyl isothiocyanate, and only people who are accustomed to use mustard oil for cooking can take foods cooked in it for any length of time without developing hyperchloridia. The Indian cook, in a similar way, loves to make every dish as greasy as possible, therefore he adds ghee, olive oil, etc., on every possible occasion, in spite of the fact that this is not the English way of cooking food. The Indian in the same way is not accustomed to the high protein diet of the European, and many of them find it difficult to digest meat in any form, but prefer their vegetarian dishes cooked in their own particular way.

(5) The fetish of exercise. In the East during the hot weather the motto of the poets is to be indolent and lie in cool places like sheltered gardens, and strenuous exercise is only indulged in during the cooler season. The European on the other hand has an idea that to keep fit in the hot weather he wants plenty of exercise and this idea is more ingrained in the neurasthenic. The result is that such strenuous games as hockey, football, tennis, etc., are played during the most gruelling time of the year with the idea that these persons keep fitter after profuse perspiration. In business cities like Calcutta the whole of the exercise for the week is taken at the week end, commencing on Saturday and ending on Sunday night. The result is that many of these office workers arrive on Monday morning tired and unable to work properly. Thus it is obvious that all these various predisposing causes play a very important part in increasing the depression commenced by the toxins of any exciting cause.

The production of neurasthenia.—The first effect of the combined action of the exciting and predisposing causes is shown by a depression of the function of the thyroid gland, a condition known as hypothyroidism. Symptomatically this hypofunction is shown by feeling cold, even in very hot weather, and such persons will require woollen garments or blankets at night time. There is also a loss of the condition of the hair, the development of alopecia along the forehead and the outer eyebrows, and the skin is slightly harsh and dry. As the basal metabolism rate is lower than the normal, so there is also a general depression in both the bodily and mental activities of these patients, except when excited under the stress of external stimuli. Coinciding with this depression of the thyroid gland we have a similar change in the adrenal medulla, so that the tone of the sympathetic nervous system is working at a lower ebb. This is further shown by a loss of tone in the whole of the involuntary muscular system; the pulse tension is low, and on pressing the skin with the nail one often sees the white adrenal line. This loss of tone occurs also in the involuntary muscles of the digestive tract, so that dilatation of the stomach (atonia) or distension of the large intestine with constipation is often present in these sufferers. On the skin, the result of adrenal deficiency is sometimes shown by the development of a slight increase in pigmentation of the face, so that these persons have a sallow muddy complexion. More rarely, there is a development of chloasmic patches on the cheeks or on the side of the neck. As the activity of the gonads is closely associated with the adrenal function, we now observe the effects of the depression of these genital organs in the two sexes. In the male there is first a loss of tone in the musculature of the vesiculæ seminales and the erector and ejaculator muscles; this is partly responsible for the lack of control and nocturnal emissions. Still later as sexual power diminishes impotence, and to a lesser degree sexual anæsthesia, develop. In the female there is a disinclination for sexual intercourse, and if anæsthesia is present partial satisfaction can only be gained by sublimation, as by narcissism, or by clandestine love.

Whilst the function of the endocrines concerned with the tone of the sympathetic nervous system is always depressed by these causes, the functions of the parasympathetic glands are not

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

affected or may even be stimulated; thus sometimes there is an increased function of the anterior lobe of the pituitary gland which is shown by the skin being very harsh, combined with the loss of body fat. If the disease starts early before the epiphyses have united, the patients are often thin and lanky. At present we know little about the changes taking place in the pituitary gland. The function of the prostate is increased, which leads to excessive secretion, and this in turn is aided by the lack of tone of the vesiculæ seminales and penile muscles. Hence there is a loss of control, which causes spermatorrhœa during the day and emissions at night. In women there is sometimes an increase in the function of the adrenal cortex, so that an excessive amount of hair (hypertrichosis) develops on the face, abdomen, and legs. As a rule the amylase function of the pancreas is diminished, so that these patients have frequently starch indigestion, and in the cases that Dr. J. P. Bose has examined for me the blood sugar has been low. Sometimes the parathyroid gland seems to share in this general depression as is shown by ulnar erythrodermia, irritability of the involuntary muscles, by twitchings of the orbicularis palpebrarum, and colicky pains in the abdomen. Twitching, cramps, and myotatic irritability of the voluntary muscles are also observed. There is a general excitability of the whole of the parasympathetic nervous system so that tremors of the hands, excessive perspiration of the hands, feet, legs and axillæ occur on the slightest mental excitement.

In Indians who are as a rule more parasympathetic than Europeans, stimulation of the prostate is more evident, whilst the functions of the pancreas and parathyroid are not disturbed to anything like the condition present amongst Europeans.

The effect on the central nervous system.—Concurrently with the depression of the sympathetic nervous system and its related endocrine glands, there is a general loss of tone and a feeling of not being up to the mark. The patient now seeks within himself the reason of his ill health. The effect of this is chiefly shown in the highest conscious centre and is exhibited

(1) By introspectiveness. This means that the patient's mind, which in normal health was not concerned with his bodily functions and only took an interest in his external surroundings, now seeks for some cause for his disease within his own body, and therefore develops a sense of visceral consciousness. As you know, normal individuals are not conscious of their heart beat, nor are the pulsations of the carotids audible to the ear, nor are we aware of any movements that occur in the stomach or alimentary canal during digestion. In these neurasthenics, the sense of visceral consciousness becomes well developed and every abnormal movement becomes more and more conscious to them. Thus when lying down in bed on the left side, the heart is felt beating, and as the attention is concentrated on this fact, the heart action becomes quickened. A sense of fear now develops that perhaps something is wrong with the heart. The rapid and more powerful action of the left ventricle makes the pulsations in the carotid arteries of the neck felt and heard. Owing to indigestion, which is often present and due to atonic dyspepsia, the pressure on the heart still further accelerates its action, and often there is an irregularity in the action of the heart at these times, so that palpitations are now noticed. The fear that heart disease has developed or is developing becomes a constant dread in the mind of the patient. The saying that most of the heart diseases diagnosed by the patient are not due to heart disease but to indigestion is very true for these cases. With the atonic condition of the large intestine and the presence of constipation colicky pains become more and more pronounced, and this gives rise to the fear that some fatal disease like cancer is developing in the abdomen. As the result of this continual dread that at some future date a fatal disease may develop and carry off the patient, a condition known as *morbid anxiety* becomes fixed in the patient's mind.

(2) Morbid anxiety. As you know, every medical student when first reading medicine in his third year imagines that he is suffering from tuberculosis, heart disease, or cancer. With an increase in knowledge and with experience these morbid anxieties disappear from his mind in a short time. With the neurasthenic individual, the morbid anxiety is developed—not without cause, but as the result of the irregular function of his various organs. He culls his medical knowledge from advertisements in the lay papers, and finally usually gets hold of some cheap semi-scientific medical publications on health, virility, etc.

Morbid anxiety in the two sexes.—In the male, at first the anxiety is nearly always concentrated on the idea that some fatal disease has or is about to develop and carry off the patient. He believes that palpitations suggest heart disease, a cough the probability of tuberculosis, the pulsating carotids rupture of a blood vessel in the brain and apoplexy, whilst indigestion is translated to be the onset of an abdominal cancer. Dread of the impending fatal disease looms much more in the patient's mind than the actual fear that death may take place at some subsequent period, should he develop this disease. Closely following the dread of a fatal disease is the fear that in addition to all these sufferings sexual impotence is developing, and this idea is aided and abetted by the many advertisements of cure for sexual deficiencies seen in the papers. Such a patient generally indulges in reading these advertisements in the hope that one or other of the more highly recommended or expensive ones will bring about a cure of this loss of strength. As a result of debility there is an increase in the quantity of phosphates in the urine (phosphaturia). These salts as you know are precipitated as soon as the urine cools, and are regarded by the patient as a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

loss of semen. The quack advertisements claim that semen is a kind of emulsion of the spinal cord and brain, and as it is lost impotence develops and the brain power fails. The loss of prostatic secretion during the day (spermatorrhœa), and the nocturnal emissions are supposed gradually to drain away the vitality of the individual. When marked debility and loss of muscular tone is present, an orgasm can only be obtained with the greatest difficulty and rarely maintained for long, unless it is caused by an extreme degree of mental excitement. As impotence develops in these individuals, it leads to still greater mental distress.

In women, the type of morbid anxiety that is developed depends to a large extent on whether they have experienced sex life or not. In married women there is very rarely any dread of disease, but very often a transferred anxiety or dread is developed, particularly amongst those who have anæsthesia and have had a child. As a result of the lack of satisfaction in sexual life, the sentiment of tenderness or love is sublimated and is transferred from the husband to the child. The women's anxiety is now fixed on the dread that perhaps some day a calamity may overtake her child, and her whole life becomes a living hell lest by accident or disease she may loose her child, and with its death the last solid link that binds her to her home. When there is no child and anæsthesia is present, the sentiment of tenderness is transferred to one of self-adoration or narcissism. At first this is satisfied by the love of self-adornment, but with increasing age there develops a dread of the loss or failure of the power to attract the male sex. The roughening of the skin, the development of pigment spots, wrinkles, grey hair, or a muddy complexion gives a fine field of profit to the patent skin food vendors, beauty specialists, and others who trade on the vanity of these women.

In single women, a dread sometimes develops that some disfiguring or loathsome disease like syphilis, leprosy, etc., may have been contracted during the course of their amours.

Excessive response to external stimuli.—This at first is often shown by nervousness in society or fear to go alone in public places like clubs, etc. This excessive response to external stimuli is more commonly seen amongst women, who must always have a male escort before they appear in public places. In society their nervousness is counteracted by an attempt at excessive hilarity, verbosity, or excessive bodily activity. At home when the same stimulus is not present a reaction occurs in these individuals, and they become morose, peevish, lacking energy, and prone to sulk; to counteract this they must be always out and about—a condition which the French have described as hyper-hypo-thyroidism, indicating that at one time the thyroid is under-functioning, but when stimulated over-functions. In males this restlessness is usually not so pronounced as amongst women, but there is often a tendency to shirk the society of women. Later still in both sexes there develops a dread of the possible effects of these external stimuli, the so-called phobias, for example claustrophobia—the dread of enclosed spaces, etc. In these individuals there is little danger of any suicidal tendencies developing owing to the fear of disease or danger which is paramount in their mind; their anxiety is to live, and by treatment to regain their health. The help they seek from our profession is the right to live in perfect health, and not to get relief by death. Depression of the higher mental functions slowly comes on. At first there is a lack of concentration, then a slow failure of memory: this stage is commonly seen in many of these sufferers. After years of suffering, of excessive stimulation by continued work, the more strenuous efforts of concentration of mind still further increase the depression, which is aided by worry, toxins, etc., and which may in time lead to the development of melancholia, and more rarely to structural changes occurring in the brain, leading to dementia.

Treatment.—The whole success of treatment depends on the fact that a complete diagnosis of the case should be made by the physician and not as is so frequently done to make only a cursory examination and to diagnose neurasthenia by the introspectiveness of the patient. A complete diagnosis often entails numerous very careful and detailed examinations, both clinical and bacteriological, before the following questions can be answered.

(1) *The exciting cause.*—Is it still present or due to some past acute disease?

(2) *The predisposing causes.*—Are they playing any active part in the depression?

When the exciting and predisposing causes have been removed by proper treatment, we have next to consider whether their after-effects are sufficiently severe to require further treatment, and which particular after-effects have to be dealt with.

The *after-effects* we observe are (1) anæmia and debility, (2) endocrine deficiencies, (3) loss of tone of the involuntary muscular system, atonic dyspepsia, cæcal stasis, etc.

Finally a complete cure depends on the ability of the physician *to deal with the mental condition of the patient.* This hinges on whether one is able to convince the patient that whatever is said or suggested is right. There should be no doubt about this in the patient's mind and then cure becomes only a matter of time. The power that was used by the patient to concentrate on and magnify the slightest irregularity of his bodily mechanism is now faithfully employed with even greater effort to aid in effecting to complete the cure that has been promised to him.

The removal of the exciting causes.—I will not attempt to give you a long list of the various exciting causes that may produce this condition of neurasthenia. I will therefore only deal with the commoner causes that I have met with in my experience. Of the acute diseases, I would place

CC-0. In-Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the enteric fevers first on the list. As you all know, after enteric fevers one of the two things may happen to your patient; he may convalesce very rapidly and put on weight, or he may remain thin and debilitated in a neurasthenic condition. Here the treatment is simple, as the exciting cause has disappeared, and all that is required is to treat the various after-effects of depression by appropriate endocrine therapy.

We have also to deal with chronic diseases, which are more often common exciting causes of neurasthenia. The importance of diseases of the alimentary canal in the tropics is very great, and they are the source of the most of the neurasthenia in the tropics. The evidence of disease in this area is so often so slight in its symptoms as to be overlooked by the physician. Thus dysentery is one of the commonest causes, and the term is correlated in the mind with the syndrome of the passing of blood and mucus, and with straining at stool (tenesmus). In chronic colitis due to the dysentery group of bacteria and protozoa there is no tenesmus, and no visible blood or pus passed in the stool, but there is *one constant sign always present, the passing of mucus.* The bowels are more often constipated than not, but there may be constipation alternating with diarrhœa, or there may be early morning diarrhœa. Except for the presence of mucus, the macroscopic appearance of the stool is not in the least suggestive of a dysenteric infection.

As the presence of mucus suggests a colitis, we have next to diagnose the causative agent.

(1) Amœbic colitis. I do not like the term dysentery for this infection, as the dysenteric syndrome is only a complication in about 10 per cent. of cases. We can diagnose the condition microscopically by the presence of mucus, pycnotic cells, Charcot-Leyden crystals, and seeing the various stages of *Entamœba histolytica* in unstained specimens—encysted forms with chromidial bars, and free forms, *minuta* and pre-adults, by their peacock green colour and their pearl-like vacuoles. When these stools are plated, there are usually found a large number of fine lactose or non-lactose fermenting colonies of streptococci or yeasts as secondary infections. There are three different lines of emetine treatment that may be employed.

(*i*) The combined treatment by alkalies orally and emetine instramuscularly or by intravenous injections. The alkalies may be given in the form of bismuth carbonate ʒi t.d.s. or sodii citras ʒi one hour before the injection of emetine. Emetine is given in one-grain doses daily for 6 days, then one to two days' rest, followed by 4 more doses, a total of 10 grains in 11 or 12 days.

(*ii*) Bismuth-emetine-iodide grs. ii by the mouth in keratine-coated tablets. The dose is preceded by omonpon $\frac{1}{6}$ gr. and when the patient becomes drowsy, the bismuth-emetine-iodide is given by the nurse. This ensures that the emetine is retained by the stomach.

(*iii*) In cases that have failed to be cured by the above methods, one advises a course of streptococcal vaccines from strains isolated from the gut, combined with an antiseptic treatment. Yatren is of value in these cases, but it is a subsidiary drug in treatment and is very expensive. As soon as the bacterial plating results show a return to a more or less normal flora, emetine and the alkaline treatment can be started at once and generally brings about a cure. I hold that the failure of emetine to eradicate *Entamœba histolytica* infection is due to the acidity caused by this intestinal fermentation of the streptococci, which will not allow the emetine to act in weak concentrations.

(2) Chronic colitis due to the dysentery group of bacilli. This condition is generally due to acute dysentery not being treated properly by sufficient rest, salines, etc. Microscopically we find mucus, degenerated shrunken endothelial cells in the mucus stained yellow by stercobilin, and usually accompanied by *Blastocystis* and sometimes *Trichomonas.* On plating, if fortunate, we may find transparent non-lactose-fermentors of the dysentery group, but in the very chronic cases dysentery bacilli are difficult to isolate. Numerous opaque non-lactose-fermentors belonging to the paradysenterica group, etc., are found on the plates. As secondary invaders of the dysenteric ulcers the *B. pyocyaneus, B. fæcalis alkaligenes* and *B. asiaticus* may be found, and still more rarely the *B. Morgani* as a cause of colitis. Sometimes we have to rely on the agglutination reactions.

Treatment consists in regulating the diet as regards carbohydrates, particularly in Flexner and Strong infections. In both types of chronic colitis—amœbic or bacillary—it is wrong to cut down the diet to too low a caloric value, as a liberal supply of easily digested foods is what the patient requires to regain his health.

The curative treatment consists in giving appropriate doses of the vaccine containing the causative agent, and any secondary organisms of the ulcers, e.g., *staphylococcus, pyocyaneus,* etc.

So far I have only dealt with the various causes of colitis, but pyorrhœa of the gums, gastric and duodenal ulcers, and sometimes the sequelæ of colitis—e.g., appendicular inflammation—have to be considered and are extremely important but are outside the scope of this paper. In these cases one ought to examine the teeth, enquire about the mastication of food, the possibility of gastric or duodenal symptoms, and carefully test for tenderness over McBurney's point. Sometimes these cases are a mixture of two or more of these diseases of the alimentary canal.

The removal of predisposing causes.—With patients who are wealthy a change to England or the hills after removing the exciting cause will deal with the whole of the predisposing causes. Unfortunately everyone is not in this position, and the majority of patients have to remain in the plains in spite of these predisposing causes.

A good deal can be done to eliminate most of them. Fans, proper dress, etc., will do much to eradicate the effects of high temperature, humidity, etc., and when one's mind is fully occupied there is little time to notice the heat, whether one is outside or inside the house, as long as a strong current of air is circulating so as to gain the advantage of the latent heat of evaporation from the sweat. I am strongly against sleeping under mosquito nets when one has a fan that is powerful enough to keep off mosquitoes.

As regards the quality of the food, its variety and cooking should be a subject that every housewife should know all there is to know about it. I have seen a few cases where the cooking has been the exciting cause, and the use of mustard oil, ghee, or lard has been sufficient to cause gastritis, and so give rise to the train of symptoms known as neurasthenia.

The treatment of after-effects.—Anæmia and debility need not be considered, as the treatment of these conditions by iron, etc., combined with good food is obvious to all of you. There are two conditions, however, which I may speak about, as in the tropics these defects are somewhat different to those seen in temperate climates.

(*i*) The endocrine defects. It is first necessary to examine the patient and find what glands have a defective function. The commonest gland involved is the thyroid, then the suprarenals, and lastly the gonads. Other glands, however, may be involved. I therefore do not believe in administering shot-gun prescriptions containing every endocrine gland of the body, but only administer those that I believe to be deficient in function. The next point is that many of these products become useless owing to decomposition in the monsoon months. They are proteins and many are hygroscopic and in a few days they become perfectly useless. The safest way to administer these endocrine glands is in the form of coated tablets, which protects them from the effects of climate. The method of administration is important, and I believe the best way is to give them by injection intramuscularly.

Unfortunately at present we have only adrenalin and pituitrin, but soon thyroxin will be available. Of the two former products I prefer to use small doses, e.g., m. ii. of a 1 : 1000 adrenalin hydrochloride and m. iv. of extract pituitrin posterior lobe once a day for five injections. After these injections I recommend that tablets should be taken by the mouth.

The doses I recommend are small doses of the dried thyroid gland, $\frac{1}{6}$—$\frac{1}{4}$ gr.; of the dried gonads grs. ii; and dried adrenal gland grs. $\frac{1}{2}$, given twice a day on an empty stomach, i.e., first thing in the morning and last thing at night, so as to avoid the action of the gastric juice on these proteins. Cases of neurasthenia that occur after acute diseases like typhoid, etc., do extraordinary well with endocrine therapy. The gland products are of very little value until the exciting cause has been removed by treatment.

(*ii*) Loss of tone of the involuntary muscles as is shown by atonic dyspepsia, cæcal stasis, etc. The condition of cæcal stasis is the more important from our point of view to consider. If visceroptosis is present we must prevent the sagging as much as possible by mechanical means such as an abdominal belt. The prevention of stasis by abdominal massage, and keeping the bowels properly emptied each day by liquid paraffin is of importance. When the intestinal flora has been considerably altered by non-lactose-fermentors, streptococci, etc., intestinal antiseptics are useful, and of these there are many on the market. Whilst the above treatment is being carried out the muscle tone may be greatly improved by the administration of small doses of pituitrin and adrenalin, combined with thyroid gland. Treatment has to be prolonged for some months before these muscles regain their full tone.

The mental condition of the patient.—Here everything has to be done by explanation, and hence it is necessary to devote some time at the beginning of the treatment to clearly explaining to the patient that the disease is not due to nerves, but due to some exciting cause that has been overlooked in his case. As soon as the poisons are prevented from getting into the body from the source, the nerves will very rapidly get into a normal condition. Advice when the sexual functions are being involved is very helpful to these patients. Psycho-analysis would be useful in those cases arising from sexual abuse, but it seems to me in most cases it would be starting at the wrong end of this syndrome, for there is always a cause, which is rarely due to a sexual one in the first place.

SUMMARY.

The subject of neurasthenia is a very big one, and I have tried to portray it as truly as I have seen it in the tropics. The exciting causes are different to those in non-tropical climates whilst the predisposing causes are also dissimilar, but can often be more easily removed by a change of climate, etc. The effect on the endocrine glands and muscular tone is similar, whilst the after-effects on the bowel are more pronounced. Introspectiveness is perhaps less marked with the easier and more varied life in the tropics, but in women the mental aspects of morbid anxiety, etc., are very much more marked by all the predisposing causes of risk of disease, separation from husband or children, etc., peculiar to the tropics.

. . . . . .

In the discussion on Major Acton's paper

Major R. Knowles, I.M.S., said that he hoped that Major Acton's most interesting paper would receive early publication and would reach a much larger audience than was present at the meeting. He had been

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

very much struck with the frequency of "visceral neurasthenia"—as one might term the condition—in Englishwomen who had lived for some years in India; also with the severity of the symptoms in some of these patients. Thus in a recent case under observation the most agonising attacks of abdominal pain had occurred off and on for nine months; an exploratory laparotomy had been suggested, but a well fitting belt had cleared up all the symptoms. As for chronic amœbic colitis, he wished that someone would tell him how to treat the condition successfully; he had been trying to discover the best line of treatment for it for years, but hitherto without success.

Major V. B. Green-Armytage, I.M.S., speaking as a gynæcologist with twenty years' experience, said that he was more interested in the study of the patient as patient than in laboratory procedures. In his opinion, as the result of searching enquiries among his patients, he thought that there were three main causes of tropical neurasthenia, viz. (*a*) masturbation, (*b*) coitus interruptus, and (*c*) sexual starvation. The view that it was due to not wearing a heavy sun topee was drivel.

In hot climates he considered that masturbation occurred in quite 70 per cent. of males in the absence of their wives at Home or in the hills. Also it was extremely common in females in the hot weather. The husband would go to office leaving the wife to secure what sleep she could in the hot weather afternoons, and this led to the practice. As for coitus interruptus the present century might well be called the contraceptive one, what with its advertisements of quinine pessaries, "Prorace" pessaries, and the like. The end result of coitus interruptus for the women was a chronic plethora of the broad ligaments, leading to a condition of varicosity akin to varicocele in the male; whilst erosions and endocervicitis followed the use of quinine and contraceptive pessaries, with absorption of toxins and consequent neurasthenia. The result of sexual starvation in the male had been strikingly illustrated by the suicides of two Englishmen in Government service in the Far East lately. Both men were in a good financial position and free from marital or other worries. But in both instances their wives had been at Home for more than two years. Under such condition, when a married man tried to lead a "straight life," he became the subject of an inferiority complex, which resulted in psychic trauma. Such cases he considered to be very common in the East.

In women narcissism was not so important a factor as the dread of child-bearing. The dread of the onset of pregnancy was the starting point of neurasthenia in many European women in the tropics. The use of abortificients by such patients led to chronic gastritis, and the cumulative effect of repeated crises during which the patient fears that she is pregnant leads to rapid nervous prostration. He considered that the sex element would account for quite 90 per cent. of the cases of tropical neurasthenia. Women with neurasthenia of sexual origin were often of masculine type.

Lieutenant-Colonel W. L. Harnett, I.M.S., dwelt upon the importance of septic foci as an exciting cause in tropical neurasthenia. With regard to the prostate, which Major Green-Armytage had mentioned, his experience was that chronic infection of the prostate was very common in European male neurasthenics, together with symptoms of "spermatorrhœa." In such cases prostatic massage and examination subsequently of the prostatic fluid expressed shewed numerous pus cells present in the discharge. There were two main types; (*a*) with gonococcus infection still present in the prostate and the vesiculæ seminales, but without neurasthenic symptoms; and (*b*) with only prostatic infection present and pronounced neurasthenia. In the latter case no gonococci could be discovered in the majority of cases, but secondary infection with pyogenic organisms had occurred. The results of proper treatment of such patients —especially by diathermy—were very striking. They experienced a sense of well-being such as they had not known for years. With regard to Major Green-Armytage's enquiry as to the physical results of masturbation in the male, he understood from published articles and text-books that examination of the posterior urethra in such cases often shewed vascular congestion present. In conclusion he would emphasise the importance of chronic prostatitis as a cause of tropical neurasthenia in the male.

Dr. G. Panja spoke of the question from the Indian point of view. Heredity was a pronounced element in tropical neurasthenia, and should not be neglected. Neurasthenia was especially seen in India women with the loss of sexual activity, also especially in Indian widows who had borne no children. In both sexes of Indians to have had no child was a frequent source of mental brooding and neurasthenia. Further contributory causes in Indian women were repeated pregnancies and lactation, and the want of exercise and fresh air consequent upon the purdah. The drug usually prescribed for the condition was mercury in some form or other, and it did but little good. He had known hypodermic injections of distilled water to hypnotise the patient into the belief that she was rapidly recovering, whilst hydrotherapy and suggestion were especially indicated.

Lieutenant-Colonel A. H. Proctor, I.M.S., insisted on the great importance in such cases of getting a full and detailed history out of the patient. This was too often neglected; the case was labelled neurasthenia and the past history entirely neglected. It might be necessary to go right back to the patient's childhood or early youth to discover important factors in the case; the sex element in neurasthenia had been dwelt upon in the discussion, and nothing but the most searching enquiries would elicit important points. Head injuries were a not unimportant cause of tropical neurasthenia in Europeans in the tropics; thus a man might sustain a "trivial" head injury at polo or when riding, and its effects translate themselves into neurasthenia. Surgical operations were a further important cause; men had a trivial surgical operation—such as an operation for varicocele—performed upon them, then went back to work before they had really recuperated, and broke down. Surgeons should learn to view their operations from the patient's point of view, and a surgical operation meant a very big amount of psychic disturbance and trauma to the patient, however trivial it might be. Tropical dysentery and chronic amœbic colitis he considered to be quite as common in the non-neurasthenic as in the neurasthenic. The great frequency of healthy carriers of *Entamœba histolytica* who never suffered from any symptoms shewed that this infection could not be so ultra-important in the ætiology of tropical neurasthenia.

In replying to the discussion, Major Acton pointed out that his paper was concerned chiefly with conditions that were more or less peculiar to the tropics, and he had no intention of dwelling upon the enormous number of contributing factors that could be present from other diseases. He considered that there was always an initial lesion which left its effect on the endocrine glands, and as a result of the depression of the body health, the mental condition of neurasthenia developed by degrees. The sexual aspects of the condition he considered were secondary, and usually the results of neurasthenia rather than the cause of it. It was quite possible for sexual causes to be the primary factor, but this was a much rarer condition. He did not agree with the Freudian view that every impulse in the body arose from a sexual motive. Reproduction was not a primary instinct in nature, but developed when food supplies were adequate for the individual and for his offspring. The primary instinct of life was self preservation, which was well illustrated amongst the cases he had seen, as these patients were usually desirous of living and getting well. He agreed that sexual starvation in the male was a contributory cause, as had been evidenced in the Eastern theatres during the war. He admitted the importance of chronic prostatitis as a septic focus leading to neurasthenia, and it was very frequently bound up with the dread of venereal disease and its effects. Psychic

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

trauma was well seen in those patients who had had many surgical operations for misplaced organs like floating kidneys, etc. The dread of the operation, the mental anxiety during its anticipation, especially with patients who are kept for hours waiting for an operation, and then sent back to be done another day was great. This influence was so strong that in persons with status lymphaticus the mere effect of a surgical examination or trivial operation was sufficient to cause death. With reference to Colonel Proctor's remarks about case histories, the patient usually gave this in full wealth of detail. Chronic amœbic colitis he regarded as one of the most important exciting causes of tropical neurasthenia, in spite of all the arguments which he heard to the contrary during the evening's discussion. He pointed out that his paper had been strictly limited to the effects of tropical diseases in the production of neurasthenia as he had seen during his experience in India.

He thanked the various speakers for joining in the discussion and putting forward their own points of view.

KETOSIS IN ACUTE FEVERS.

By H. HINGSTON, M.D.,

MAJOR, I.M.S.,

Officiating First Physician, Medical College Hospital, Calcutta.

It has long been known that during the course of an acute fever ketone bodies may appear in the urine. I do not think it is generally recognised that this occurrence means that an important pathological disturbance of metabolism is present, and that it is a real indication for special treatment.

Further, I am firmly convinced that this disorder of metabolism is the cause of many of the more acute symptoms seen in these fevers and usually attributed to "toxæmia." It has been my privilege during the last year to have many cases of enteric group infections, pneumonias, septicæmias and similar diseases under my care. In all these diseases nervous symptoms of varying severity are sometimes the most difficult symptoms with which the physician has to deal.

Headache, delirium, muscular twitchings, picking at the bed clothes, insomnia (especially in pneumonia) are all conditions which indicate a derangement of the nervous system.

A routine examination of the urine for acetone very definitely shows that when these symptoms are present there is in almost all cases a very marked acetonuria.* In fact I have not seen these symptoms without acetone in the urine except in very severe infections as a terminal manifestation. A more important and a very striking clinical fact is the rapid disappearance of these symptoms when treatment is vigorously carried out to combat the ketosis.

Before discussing the treatment it may be advisable to attempt to explain the pathological conditions underlying the appearance of acetone and diacetic acid in the urine. I know only too well that the whole question is complicated and difficult, and that the following explanation will not satisfy the biochemists in its entirety. Still it is logical and simple. It is the explanation that I give to the enquiring student, and above all, it forms an excellent argument for the treatment adopted.

The basis of the argument is that in these cases the presence of ketone bodies in the urine means the presence of oxybutyric acid, diacetic acid and similar acids in the blood, and that these acids must be formed by the incomplete metabolism of fats. The old explanation that satisfactory metabolism of carbohydrates is necessary for the complete metabolism of fats still holds good; in fact the sugar is the fuel that burns up the fats.

In these cases the patients are wasting rapidly. A man with typhoid fever may lose two pounds a day and it is clear that the greater part of this loss is in the fatty tissues of his body. It is the same as if he were using up a great quantity of his fat. It must be efficiently oxidised or the acids of incomplete metabolism will appear in his blood.

Now these patients are receiving little food in most cases, and they certainly are not obtaining sufficient carbohydrate to burn up the excess of fat that is undergoing metabolism. This explanation immediately leads one to a simple and effective method of treatment; the administration of glucose and alkalies in comparatively large quantities.

It is probable that as a routine measure in these cases for many years alkaline mixtures have been the most popular medicines. During recent years the administration of glucose has been vaunted and more especially the intravenous injection of glucose solutions in pneumonia.

The alkalies have been considered to be effective diaphoretics and diuretics and glucose a heart stimulant, but I cannot remember having heard that their efficiency may be due to their effect in combating the ketosis that is present, although I am of opinion that this is by far their greatest—if not their only—claim to therapeutical importance. I also think that those physicians who have claimed that severe toxic symptoms are rare in such fevers as typhoid when the patient is given a good mixed diet are dealing with this ketosis in a similar manner.

The method of treatment that I have adopted during the last year is simple in the

---

*The word acetonuria is convenient and in common use and in this paper has been used throughout to indicate the presence of ketone bodies in the urine; chiefly diacetic acid—as tested for by Rothera's method.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

extreme and is very satisfactory. The alkaline mixture used is:—

Potassium citrate	2 drachms.
Liquor of ammonium citrate ..	2 drachms.
Sodium bicarbonate ...	30 grains.
Spirits of aromatic ammonia	30 minims.
Water up to 1 ounce.	

One ounce of this mixture is given in 2 ounces of water every four or six hours according to the severity of the symptoms and the amount of acetone in the urine, as judged by the rapidity and depth of colour by Rothera's method. Two drachms of glucose are given every two or four hours.

In twenty-four hours the acetone has disappeared from the urine and in the great majority of cases the condition of the patient has vastly improved.

The patient is then given a simple alkaline mixture three times a day and two drachms of glucose every six hours.

A patient admitted with typhoid of ten days' duration will be delirious and semi-conscious. He will be picking at his mouth and at his bed clothes. His tongue will be dry and his pulse weak and perhaps rapid.

In thirty-six hours all this will be changed and he will be lying quietly, sleeping most of the day and night, and in fact will be the type of case that we all like to see and that causes us no anxiety.

A similar result is seen in severe pneumonias. Of course this treatment will not shorten the duration of the disease, whatever it may be, neither will it forestall the complications that may ensue, unless "toxæmia" is considered a complication. It certainly does lessen the nervous symptoms and changes the whole aspect of a bad case, if the treatment is commenced sufficiently early in the disease.

The attached table shows the last twenty consecutive cases of typhoid fever under my treatment in this hospital.

In addition to these, two patients were brought to hospital extremely ill and suffering from what appeared to be typhoid fever as judged by the history and clinical symptoms. They both died shortly after admission, before pathological investigations were carried out, and are therefore not included as proved cases of typhoid fever.

In addition to the medicinal treatment outlined above, the further treatment of our typhoid cases was very conservative. The diet was invariably milk, and if any symptoms of abdominal distension or diarrhœa ensued only lime whey was given. As much fluid in the form of water as the patient would take was also given. I could not discover that the glucose caused any indigestion or flatulence but I formed the opinion that it was an important factor in preventing great loss of weight and prostration.

It is not claimed that this method of treatment greatly lessens the mortality or the appearance of complications in typhoid fever, but I am certain that it is as simple and as logical and as effective as any. Certainly during the last year I have not seen a patient who remained in the "typhoid state" for more than thirty-six hours after the treatment was started, although many arrived in hospital with marked nervous symptoms associated with acetonuria.

The cessation of these symptoms is just as marked in other septicæmic conditions and in pneumonia.

Although it is rather outside the scope of this paper, there may be some interest in analysing the pathological findings in these cases. The number is admittedly very small, but I think it fairly summarises our experience of the much greater number of cases seen during the year.

In this series only the routine hospital examinations were carried out and no special investigations were made with a view to publication or clinical research.

The hospital routine in all cases that may be enteric group is as follows:—

(1) The urine is examined and total and differential leucocyte counts are made in the clinical laboratory. Malarial parasites, if present, would be noted during this examination.

(2) On the day following admission blood is taken from a vein and is cultured for bacteria and for Leishmania flagellates and a portion reserved for agglutination reactions. If it is considered necessary, either from the history or symptoms, the formolgel test and the Wassermann reaction may be done.

(3) On the third or fourth day, when the patient has settled down, Marris' atropine test is done (vide *Indian Medical Gazette*, Dec. 1926).

(4) Later, in some cases examinations of the urine and stools are made for the presence of the *Bacillus typhosus*.

(5) Agglutination reactions are carried out at a later date if the previous ones were at all doubtful. A positive reaction of 1 in 125 by Dreyer's method is considered sufficient to make a definite diagnosis in a non-inoculated patient, even if all other tests are negative. The reverse is by no means true.

In this short series of twenty cases the following points will be noticed.

(1) Acetonuria was present in eleven cases. These were clinically the more severe cases. The average duration of disease on admission in these was 12.5 days, and in those without acetonuria 7.3 days. Every patient admitted on the 12th day or later showed acetonuria.

Patient No. 15 was admitted on the 11th day without acetonuria. It was a very mild case.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

He was walking about and was taking a fair diet.

(2) Blood cultures were positive in 14 cases and were negative in 6. Of these six cases, one culture was contaminated; one and sometimes in association with a growth of *B. typhosus.*)

Two were taken after the 20th day.

Two were negative on the 8th and 12th day respectively.

*B.C. + = Blood culture positive to *Bacillus typhosus.* Organism proved by sugar reactions and agglutination by standard serum.
St. + and U + = Stools and urine cultured show growth of *Bacillus typhosus* proved as above.
Agl. + = Agglutination by Dreyer's standard method positive.

grew a streptococcus. (This has occurred previously on several occasions in proved typhoid cases, sometimes as a pure growth

(3) Urine cultures were done in eleven cases during active disease.

Eight were positive and three negative.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(4) Stool cultures were done in 12 cases. Five were positive and seven negative.

(5) Agglutination reactions.

Three were negative early in the disease (8th day or less) but became positive later. On the other hand, other cases as early as this were very definitely positive.

Cases 12 and 15 are of interest. Although definitely proved to be cases of typhoid, the agglutination reactions remained negative throughout the disease and during convalescence. This has happened previously during the year.

Conclusions.

Certain conclusions can be drawn even from this small number of cases.

(1) The examination of the urine for acetone and diacetic acid is of extreme importance and forms an important basis for treatment.

(2) None of the pathological investigations are infallible. Blood culture is the most reliable method early in the disease.

(3) Culture of the urine is much more frequently positive than culture of the stools. This is of importance in connection with the examination of carriers.

(4) The agglutination reaction in most cases becomes positive as the disease advances, but may remain negative throughout convalescence.

I have to thank Lieut-Col. Holdich Leicester, I.M.S., acting Principal of the Medical College, Calcutta, for permission to publish these cases, and Major G. Shanks, I.M.S., under whose supervision the pathological work was carried out.

A NOTE ON THE PARASITE OF "DERMAL LEISHMANOID."

By Assistant Surgeon B. M. DAS GUPTA,

Assistant Professor of Protozoology, Calcutta School of Tropical Medicine.

THE condition known as "dermal leishmanoid," first described by Brahmachari (1922), has now become a commonplace at the Calcutta School of Tropical Medicine. Every month some three or four such cases are seen in Major Acton's skin outpatient clinic at the School and are sent to the Protozoology Department for examination.

The history of these patients is a typical one. In the great majority of cases they have suffered from kala-azar for which they have been successfully treated with antimony injections, with complete recovery. Some months—or more usually years—later tiny leucodermic spots appear on the skin, especially of the face, forearms, trunk, and in the case of the male of the scrotum. This is followed by the development of soft non-ulcerative granulomatous lesions. The final appearance of the patient is often suggestive of nodular leprosy, whilst one recent case—illustrated in the *Annual Report of the Calcutta School of Tropical Medicine* for 1925—simulated xanthoma tuberosum multiplex, and the condition had lasted for sixteen years.

In a few instances no history of previous kala-azar can be obtained, but all the patients come from kala-azar endemic areas. Apart from the skin lesions their general health is normal, and the laboratory findings are always the same. Films from the lesions show leishmania, sometimes in very considerable numbers, sometimes in only scanty numbers, whilst cultures from the lesions give a rich growth of the herpetomonad form of *Leishmania.* Cultures from the patient's peripheral blood for leishmania are invariably negative, and on those occasions when an enlarged spleen permitted spleen puncture, films and cultures of spleen juice have invariably given a negative result. The condition thus appears to be one of purely cutaneous leishmaniasis, associated with no visceralised infection.

Is the parasite which causes these lesions *Leishmania donovani* or *Leishmania tropica*?

The whole trend of the clinical evidence goes to show that it is *Leishmania donovani.* The association of the disease with kala-azar, and the distribution of the lesions on the body are evidence for this. The lesions themselves are of a proliferative granulomatous character with no tendency to atrophy of the skin or to ulceration—(except in some instances in the scrotum where irritation has occurred from the clothing, with secondary sepsis).

The following experiments in connection with one of these patients shew that the leishmania parasite concerned in this infection is capable of causing a generalised, visceral infection.

The patient, a Hindu male, aged 27 years of age, was well nourished and had no enlargement of the spleen or liver. He had kala-azar three years ago, was treated with antimony injections, and made a complete recovery.

On examination, small leucodermic spots were present on the forehead and chin, and a few small nodules on the left ear. The duration of the condition was about two months.

One of the nodules was painted with tincture of iodine and then with alcohol, and a tiny piece of the growth snipped off with fine scissors and placed in a sterile Petri dish. This was next cut into three bits. Two were sown direct into the water of condensation of NNN medium, whilst films were prepared from the third piece. Scanty leishmania were found in the films.

The NNN cultures were incubated at 22°C., and shewed no growth on the fourth day. On the twelfth day, however, both cultures shewed positive results. Films were

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

prepared, fixed over osmic-acetic acid vapour and stained with dilute Giemsa's stain (Shortt's technique, 1923). Many flagellates were found, both free and in rosettes, together with some rounded forms shewing badly staining nuclei and probably degenerating.

Next day the water of condensation of one of the tubes was diluted with a little citrated saline, aspirated into a hypodermic syringe, and the material injected intraperitoneally into two (English) white mice.

One of the mice was killed 94 days later. Its spleen was found to be enormously enlarged, the other organs being apparently normal. A culture was taken from its spleen by the following technique:—

The body of the animal is placed on its back on a tray of paraffin wax, the surface of which has been previously washed with lysol, and the legs fastened down with pins.

The fur of the chest and abdomen is cut short and the skin thoroughly painted with tincture of iodine. The abdomen is opened with fine scissors and an assistant holds aside the abdominal walls with sterile forceps. With fresh fine sterile scissors and forceps tiny pieces of the spleen and liver are snipped off and immediately dropped into the water of condensation of tubes of NNN medium.

Prior to using this technique I have twice tried the method recommended by Christophers, Shortt and Barraud (1926) of grinding and emulsifying the tissue in saline and inoculating the NNN tubes with the emulsion, but on both occasions all the cultures taken became contaminated. With my present technique contamination has never occurred.

The cultures from the spleen and liver of this mouse showed scanty flagellates present on the 18th and 19th days, together with a large number of aflagellate forms. In sub-culture there was a fairly rich growth, and the strain has been maintained by sub-culture.

Smears were also taken from the heart blood, spleen, liver, and bone marrow, but showed no parasites. The films of the heart blood showed marked basophilia, but this is not an abnormal finding in the white mouse.

The second mouse died at night, 95 days after inoculation, and was not examined, as its organs were decomposed the next morning.

The fact that the *Leishmania* parasite concerned in dermal leishmanoid is thus capable of producing a visceralised infection in a susceptible animal goes to show that it is *L. donovani*, and not *L. tropica*.

A SIMPLE METHOD OF DEALING WITH DESTRUCTIVE LESIONS OF THE LIDS.

By R. E. WRIGHT,

MAJOR, I.M.S.,

Superintendent, Government Ophthalmic Hospital, Madras.

A MALE Hindu patient was admitted to hospital with a large crescentic slough involving the whole of the lower lid except a narrow rim close to the lashes. The limit of the damaged area lay over the inferior border of the malar bone. A smaller crescentic area of the upper lid was gangrenous. The damage had been produced by irritant remedies applied over the eye as a plaster. This method of treatment is not infrequently adopted by village quacks for acute conjunctivitis and other infections of the eye, and the practitioner may find the results very difficult to deal with. In spite of the greatest care, extensive ectropion is liable to set in rapidly, followed by exposure ulcer of the cornea and panophthalmitis. Even to the eye specialist, the plastic procedures which may be adopted to meet these sequelæ present considerable difficulties, so that any simple means of preserving the eye and maintaining its function should be of general value under such circumstances. The case recorded illustrates perhaps the simplest method of dealing with a condition of this sort. The damaged area was exceptionally big; so the decision as to the type of plastic operation to adopt was left over for consideration and immediate treatment confined to tarsorrhaphy. The lids were brought together in their middle two-thirds in the usual way, considerable care being exercised in dealing with the narrow skin margin above and below the lashes. They united well and the stitches were removed as soon as possible, no damage being done to the skin rims by sutures or beads. In dealing with such lesions one has the choice of many operations and some of them are very valuable. We have practised here various types of flaps, epithelial outlays, and so on, but all such procedures offer considerable difficulties and are for the most part out of the question for the practitioner who has no special facilities. It was at first thought that an extensive plastic operation would be necessary. As time went on, however, it became apparent that the cicatrices were going to be smaller than was anticipated, and the narrow belts of skin which bordered the lids' margins had extended upwards and downwards to quite a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

considerable extent. Finally it was decided not to excise the scars or do anything further than merely open the lids at the junction of the inner and middle thirds for a short distance just enough to enable the patient to see. This was carried out, and the patient was kept under observation to determine whether a partial ectropion would occur or pouting of the conjunctiva would obscure the aperture. Nothing of the kind happened and although the cosmetic result was indifferent, the function was excellent.

A pair of spectacles would have obscured the unsightliness of the scar to a great extent. The tarsorrhaphy had preserved the eye as well as the most elaborate plastic done by a specialist accustomed to such work would have done. For this reason I think this case is worthy of record as these lesions are not uncommon in India and they almost certainly result in loss of the eye unless dealt with promptly. Such injuries must be very puzzling to those unaccustomed to deal with them, and it should be a great source of satisfaction to any practitioner who has had to watch an eye gradually going towards destruction from exposure to know that a good result may be obtained even in an extensive case by a simple method. I consider that tarsorrhaphy is one of the operations which all students of ophthalmology should learn and I invariably lay stress on it. There are numbers of conditions in which a timely tarsorrhaphy may save an eye. One has only to mention such examples as the lagophthalmos of leprosy, the keratitis after interference with the Gasserian ganglion, exposure of the cornea due to tumours of the orbit, and the cicatricial ectropion group as instanced above, to show the importance of mastering this simple piece of operative technique.

THE TREATMENT OF HEPATIC ABSCESSES OF AMŒBIC ORIGIN.*

By S. N. HAYES, F.R.C.S.,
CAPTAIN, I.M.S.,
Professor of Surgery, Prince of Wales Medical College, Patna.

The object of this paper is twofold:—

1. To show that liver abscesses can be cured by emetine alone.
2. To suggest definite rules for their treatment.

Sir Leonard Rogers in his Lettsomian Lectures, reported in the *Lancet* of March 11th, 1922, p. 465 *et seq.*, gives a masterly statement of his researches. He states that single or multiple abscesses can be cured by simple drug treatment, and that abscesses can be converted into sterile encysted liver abscesses. He does not mention, nor can I find any mention in the literature at my disposal, the ultimate fate of these "cysts."

The indications for treatment given in the literature leave much to be desired, and I consider that we ought to be able to divide abscesses into classes, each of which would receive its own particular form of treatment.

My own interest in these cases was aroused two years ago by not being able to operate on a case, and ordering emetine injections instead. To my surprise the man recovered and left hospital quite well. Since then I have only aspirated and opened abscesses for the purposes of demonstration, and have come to the conclusion that the large majority of abscesses can be cured by drug treatment alone.

There are certain facts regarding liver abscesses to be kept in mind:—

1. That 75 per cent of them are sterile.
2. That of the remainder, many contain organisms of very low virulence.
3. Emetine is a specific for *Entamœba histolytica.*
4. Abscesses may be single or multiple; the latter I believe to be far commoner than one imagines.

The present methods of treatment are:—Emetine injections, plus (1) open operation; (2) siphon drainage; (3) aspiration; followed by a course of bismuth emetine iodide.

Emetine Injections.—The important question is:—What is the actual power of emetine on a liver abscess? We know it kills the amœbæ and causes encystment of the pus, but what happens afterwards?

The following cases provide the answer and Case 1 definitely shows that the cyst will be absorbed and that the clinical result is excellent.

Case 1.—A. S., aged 35, mendicant. Admitted 4th August 1926; discharged 8th September 1926. Complained of fever and swelling in the abdomen, of 1½

* Being an abstract of a paper read before the Patna Medical Society on October 29th, 1926.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

months' duration. Great pain in the right side. Pain on pressure over the liver. Temperature 98.4° to 102°F., pulse 100. Blood count—W. B. Cs. 12,000.

Treatment.—Emetine gr. 1 daily for 8 days.

The temperature became normal after the second injection. All pains disappeared. On August 13th and 14th the temperature rose to 101°F.; after that it was normal throughout. A second course of 8 injections was given from 1st September 1926. He was fit for discharge after the first course, but was kept in hospital for observation. Although on discharge his liver was easily palpable (*vide* photo), at the time of writing, 21 days after discharge, it was not palpable.

This case is the only one which I have been able to follow up. There is no doubt that he had an enormous abscess, neither is there any doubt that at the present time his liver is not palpable. It would be difficult to say from his present condition that he had suffered from liver abscess.

Case 2.—D. C., Hindu shopkeeper, aged 40. Admitted 21st August 1926; discharged 27th September 1926. Complained of dysentery, cough, and pain on the right side. Liver enlarged 4 inches below the costal margin. Given 8 injections of emetine, gr. 1 daily. Discharged at patient's own request on 27th September 1926, the liver on that day being 1½ inches below the costal margin.

Case 3.—S. S., Hindu cultivator, aged 28. Admitted 1st September 1926; discharged 18th September 1926. Admitted to the medical wards for treatment of cough and pleurisy. Complained that about 10 days previously he commenced coughing. Also complained of pain in the chest when breathing, and pain in the abdomen after defæcation. General condition emaciated. Was unable to lie down in bed owing to the difficulty in breathing. Was generally found leaning against the wall.

On examination the right side of the chest was dull on percussion and breath sounds were absent. The liver was enlarged one hand's breadth below the costal margin. A bulging swelling was present in the epigastrium.

Chest aspirated. Clear yellowish fluid withdrawn which was sterile. Total leucocyte count, 12,500 per cm.

Treated by 12 injections of emetine, gr. 1 daily. The temperature from 1st to 13th September varied between 98° and 101°F., after which it was normal.

Discharged at his own request. Liver two fingers below the costal margin. No fluid in chest on aspiration.

I am indebted to Lieutenant-Colonel H. Dutton, I.M.S., for the notes of this case.

These cases are typical of many and I think one is justified in stating that when the amœbæ are destroyed the pus will rapidly be absorbed.

Open operation.—This method is still described at great length in many books on operative surgery. In my opinion it has no place in the treatment of liver abscesses. No open wound can be kept sterile. To open a sterile abscess knowing that the cavity will become infected is an operation incompatible with present day knowledge. Its place is taken by—

Siphon drainage.—This means drainage through a tube from the abscess to a bottle containing antiseptic fluid which covers the end of the tube. The bottle is placed lower than the abscess.

The indications for its use are those abscesses which resist other methods of treatment, i.e., infected abscesses, and those in which aspiration has failed to evacuate the pus.

Aspiration.—This is the method advocated by Rogers and the one which is mostly used at the present time. Surgically it is ideal. It empties the abscess whilst emetine kills the causative organism. But for multiple abscesses it is useless (as is any form of operation). In many cases the pus will not flow through the cannula. Nowadays abscesses of a large size are uncommon. The literature of the past was filled with 50 oz. abscesses, and 5 oz. was an uncommon size. Now the positions are reversed.

Case 1 shows the result of emetine alone in a very large abscess. Why then use any other method in a smaller abscess? Aspiration of large abscesses is easy and safe, but in the case of small abscesses it is an operation requiring a knowledge of the anatomy of the abdomen and thorax which is not possessed by all.

It is reasonable to assume that a liver enlarged two-finger breadths below the costal margin can be reduced by emetine alone, and this is actually my own experience.

The method of measuring by fingers serves as a rough guide for treatment.

One can then conclude as follows:—All abscesses enlarging the liver less than two-finger breadths below the costal margin may be treated by emetine alone; those more than two-finger breadths by emetine plus aspiration. There will naturally be a large number of border line cases with such a rough indication and I think that you will find that you will tend to use aspiration less and less, and only use it in those cases (1) in which you feel definite fluctuation; (2) which resist emetine alone; (3) which extend more than a hand's breadth below the costal margin.

Summary of Treatment.

1. For all cases with the liver enlarged up to two-finger breadths below the costal margin—emetine injections alone. I give two courses of gr. 1 daily for 8 days, with an interval of one week between. After the first course the patients are usually well enough to attend as outpatients.
2. For cases with a greater enlargement or a definite fluctuating swelling, or resisting emetine alone—emetine plus aspiration.
3. For cases not responding to the above—emetine plus siphon drainage.

All patients should follow this up by a course of emetine bismuth iodide gr. 3 daily for 12 days.

INJURIES OF THE KNEE-JOINT.

By SIR JAMES R. ROBERTS, C.I.E., M.B., M.S., F.R.C.S. (Eng.),

LIEUTENANT-COLONEL, I.M.S. (Retired).

Important Anatomical Points.—The bones concerned are the lower end of the femur with its deep intercondylar notch; the upper end of the tibia with its spine, to which are attached the crucial ligaments; the upper end of the fibula, its articulation with the tibia and the insertion of the biceps tendon; the patella with its relation to the quadriceps tendon and its smooth posterior surface.

Ligaments.—These are the capsular, external and internal lateral, ligamentum patellæ, crucial ligaments preventing anterior and posterior movements of one bone on the other, but permitting of flexion and extension, and when the knee is flexed at a right angle allowing of a certain amount of rotation. This rotation is important to remember as will be shown later; it should be produced in the normal subject in order to familiarise oneself with the amount.

The *semi-lunar cartilages* are attached by their outer margins, free internally, with narrow anterior corners and broad bulbous-like posterior corners.

Tendons.—Those of the biceps and semi-membranosus muscles—with bursæ, often communicating with the joint; the tendon of the quadriceps and ligamentum patellæ—with bursa—lie under the latter.

The synovial membrane on a basis of fibrous tissue affords a lining to the joint, and is reinforced in front by pads of fat on either side of the patella; these pads project so as to fill up the spaces left by the rounded ends of the two articulating bones.

It is not proposed to deal with fractures into the knee-joint.

Injuries and methods of production.—It is important to ascertain the manner in which the injury has been produced, and the patient must be most carefully questioned, as an obscure point in the exact diagnosis may often be cleared up by this means. Thus:—Was the joint in a position of extreme extension and then twisted, or was it semiflexed and twisted? The twisting is more often produced by the weight of the body thrown to one side or the other, as when a football player is borne to the ground with the knee in extreme flexion and the body twisted round.

Wrenches in which strain is put on the external or internal lateral ligaments cause tearing of these. In twisting movements strain is especially put on the crucial ligaments and on the external attachments of the semi-lunar cartilages.

Method of examination.—Note the gait of the patient; does he walk on the toes of the injured limb because the joint is painful in extension, or cannot be extended; or is the joint locked and the patient unable to put the foot to the ground? Examine the patient by placing him prone on a full-length couch, with both legs exposed for the purposes of comparison. Note the amount of swelling and "traumatic effusion" into the joint; fluid in the joint can be delicately ascertained by the floating patella test, i.e., fixing the quadriceps tendon with the left hand, and placing the tips of the fingers of the right hand on the patella; then by a series of sharp pressures feel whether the patella lies directly on the bone, or is separated from it by a layer of fluid. This must be practised by a beginner on normal joints in order to gain familiarity.

It is most important to test the extension of the joint, and whether it can be forced back to extreme extension as in the opposite limb, and whether if this can be done, it is painful or not. Knees with unrelieved derangements cannot be completely extended. In order to do the test, put a pillow under the patient's heels so as to raise the knees, leaving a space between them and the couch. With one hand on each knee force both backwards, and compare the two, watching the patient for signs of pain. *Another method* of testing the extension is to place two chairs side by side at a distance of 18 inches apart. The surgeon sits on one and the patient on the other; the latter then turns half left and places both limbs on the surgeon's lap, leaving the knees unsupported between the chairs, when the test for complete extension can be carried out. There are important decisions to be made by the surgeon on this test, e.g., whether the joint is cured, and what amount of exercise or games the patient is to be allowed.

This is the place to make a remark on the subject of "synovitis"; this term should be relegated to cases of arthritis, and not to injury. In these latter it is proper to describe the swelling as due to "traumatic effusion," not synovitis.

The test for antero-posterior mobility in cases of complete rupture of the crucial ligaments can be made as follows:—The patient being seated on a chair, the surgeon grasps the thigh with one hand, and curls his other hand and arm round the leg, so as to bring his wrist upon the upper calf, he then pulls the leg backwards and forwards, and notices whether the tibia is movable on the femur or not. If not, the crucial ligaments are intact.

Injury to the External Lateral Ligaments.—This is the less common, but is often associated with fracture of the head of the fibula, below the attachment of the tendon of the biceps; ascertain this point. Injury to the external lateral ligament gives rise to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

local tenderness and may be followed by a cystic condition of the bursa connected with the biceps tendon. This bursa may connect directly with the joint. An ununited fracture, which is likely to occur, if overlooked, can be treated by open operation; freshening the two fractured surfaces, turning down a strip of the vastus externus tendon, but leaving it attached at its lower end; vertically drilling the head of the fibula, threading the tendon strip through this; then drilling the shaft for three-fourths of an inch or so, and making a side connecting hole through the wall of the shaft. Along this curved passage the strip is made to pass and tied above the head of the fibula to the tendon there.

Injury to the Internal Lateral Ligament.—Injuries to this ligament are not uncommon, especially since ski-ing became popular, and can be diagnosed by the swelling and seat of pain, the mobility produced and the traumatic effusion. Complete extension of the knee-joint is painful and even impossible. It is important to remember in connection with this injury that trauma is inflicted on muscle attachments and that effusion occurs above the internal condyle of the femur. In common with injuries to muscle attachments near joints—such as the brachialis anticus—ossification is likely to take place, and a protracted convalescence ensues, only to be hastened by removal of the osseous deposit. Thus injury to muscles near a joint produces the so-called "myositis ossificans." It stands to reason that early massage of the swelling after injury to the internal lateral ligament can only make matters worse, and it is only after prolonged rest, when recovery has set in that a little final massage can be tried. Here it is that *x*-rays prove their value in demonstrating this bony condition, deposits of which can take place both in the injured lateral ligament and above the internal condyle of the femur.

Fracture of the spine of the tibia.—The fractured spine takes with it the attachments of the crucial ligaments, and is an example of how bone often gives before ligaments. The diagnosis is easy owing to the mobility; but the differential diagnosis between this and ligament rupture is dependent on an *x*-ray photo. The treatment is prolonged rest in easy flexion, for if the knee is kept extended the spine is drawn from its head by the crucial ligaments.

Rupture of the crucial ligaments is usually associated with so severe an injury that the whole complex will require careful and well thought out treatment by position, rest and apparatus.

Injuries of the semi-lunar cartilages.—It is to be remembered that these structures are narrow at their anterior ends and broader and bulb-like at their posterior ends, and are attached to the capsule and bone along their outer margins. Dislocation of these cartilages means a splitting along the outer margin leaving the anterior and posterior ends intact and fixed; or it may be that either the anterior or posterior end becomes detached. In the first case a strap, as it were, is free—though attached in front and behind—to move between the articular surfaces, or to be pushed into the intercondylar notch of the femur. Once in this position it may remain there and cause no more trouble, but usually it is displaced again into the joint cavity and locks the joint. Many cases of dislocated cartilage are cured by bone-setters' manipulations; this is due to their having succeeded in forcing the cartilage up into the notch.

The signs of dislocated cartilage are locking of the joint, interference with expansion, and sometimes a history of previous replacement by efforts on the part of the patient. With the original dislocation effusion is marked, more so than in the subsequent ones. The patient complains of intense pain at the time of the displacement, and tenderness over the attachment of the cartilage. It is not always the case that external cartilage dislocation can be differentiated from internal, as injury to the former may also give rise to pain internal to the patella, though as a rule the discovery of tender spots on either side of the patella gives the clue.

The treatment of displaced cartilage is either by manipulation or operation. Here one may refer to immediate treatment or first aid. Thus were one present at a football match, where a player injures his knee, proceed as follows:—lay the patient on his back; seize the limb by the ankle or foot; bend the limb to a right angle and rotate the tibia on the femur from side to side, not once but many times in succession. This is almost certain to replace the cartilage from between the bones, and is to be followed by extension. If this can be done the rotation has been successful; if not, try again; but if unsuccessful it is a case for *x*-rays and probably operation. After reduction the treatment is one of fixation, rest, etc., remembering that the cartilage will take some time to regain its firm attachment. Should this not be accomplished the case is then one for operation.

Cartilage injury.—For some unaccountable reason, a piece of articular cartilage covering the femur, tibia or patella may become separated and form a loose body. An erosion is left behind at the site of detachment. This injury is difficult of diagnosis, as the symptoms are milder, the disability only feebly crippling to the patient, unless a large loose body catches between the femur and tibia. Such cases are only cured by operation. Removal of the body can be done, but it is important to examine the articular surfaces in order to discover the pit, and if its edges

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

are undermined to cut away these—bevelling them as it were.

Synovial membrane fringes.—These fringes hypertrophy, and the edges get nipped between the bones, or cartilaginous and osseous nodules form in the fringes, subsequently to be detached and form "loose bodies" in the joint. These cases are generally over 30 years of age. Some persons have permanently creaking knee-joints and crepitus can be felt by a hand placed on the joint while it is being flexed and extended. Nipping of a fringe is followed by traumatic effusion if not relieved and prolonged treatment is required. The accident is sudden and painful, and the patient comes into the surgeon's room limping on the toes of the injured side. The movements made in walking, jumping, playing tennis, etc., are the direct causes. The fringe when nipped requires to be freed—the sooner the better. This is done by rotation from side to side when the knee is bent at a right angle, as previously described. The relief is immediate and a bandage should be worn for a few days to support the joint. The patient can be instructed in the manipulation of replacement to meet a future occasion.

Enlargements of the bursæ of the biceps and semi-membranosus tendons are likely to communicate with the joint. For the first treatment simply evacuate; if it refills dissect it out; if again unsuccessful the joint requires to be opened and the synovial membrane in the vicinity examined, and if diseased scraped away.

Supervention of malignant disease after injury.—In young persons it is important to remember that an injury to the knee-joint may be the starting cause—though this is rare—of a sarcoma of the lower end of the femur or tibia. A patient after prolonged treatment without improvement, is dissatisfied, sees another surgeon who *x*-rays the limb and makes the diagnosis. Non-diagnosis of malignant disease in its early stage is a serious matter and emphasises the necessity of an *x*-ray photo in all cases that are obscure, or who do not begin to improve from the first.

Supervention of tuberculous disease after injury.—This is another important contingency to be remembered, and the importance of an *x*-ray examination is here again emphasized.

This paper is not one dealing with arthritis; but it is to be remembered that pain down the inner side of the head of the tibia points to arthritis, and to bear in mind the association of pain in the knee with hip disease.

Operation on the knee-joint.—A vertical incision through the skin and capsule is better than an L-shaped one, lest the capsular ligament be injured in the horizontal incision of the L. The capsular incision should not be placed immediately under the skin incision, for fear lest the buried sutures of the capsule make contact with those of the skin and a channel for infection be created. As many as three incisions can be made if found necessary. The first in front, to explore the anterior portion of the semi-lunar cartilage; if this is intact then a posterior incision is made to deal with that portion of the cartilage. Put up the limb in a slightly flexed position, and on removal of the stitches allow the patient to get up. Within a fortnight allow him to discard a splint and move about the house, giving massage to the muscles in order that they may retain their tone, and so be prepared to protect the joint. These cases do not require a long convalescence. To split the patella vertically in order to expose the joint is barbarous surgery, as chronic disability is so apt to be left behind. Hæmorrhage into the knee-joint owing to injury or operation can be recognised by a rise of temperature. In knee surgery there is no margin except for the strictest aseptic surgery, as there is no more vascular part of the human anatomy.

BERIBERI: ITS SYMPTOMS AND TREATMENT.

By A. E. COYNE, M.D., L.R.C.P., L.R.C.S. (Edin.),

Superintendent, Gifford Mission Hospital, Nuzvid, Kistna District.

SYMPTOMS.

Dry Beriberi.—This form usually begins with some burning in the stomach, and tingling in the legs and feet and sometimes in the hands. After one or two days pains occur in the legs, at first being only slight, but becoming quite annoying within three or four days. The calf muscles are especially painful. The tingling gradually increases in intensity and also spreads over a greater area, affecting the hands and arms. The tingling is most intense in the soles of the feet and in the palms of the hands. Sometimes it is also intense in the lower abdomen, and some patients complain of a tingling sensation in the tongue. The pains in the abdomen increase and there is a sensation of tightness around the waist, as though a band or belt was tied tightly. Along with the tingling in the legs, there is a considerable amount of tightness in the muscles of the thighs, causing a feeling as though cords were pulling when the legs are stretched out straight.

On pressing on the calf of the legs considerable tenderness is complained of, and there is usually a slight amount of œdema over the shins. The feet are also swollen in the more severe stages of the disease. As the disease progresses the patient becomes very weak, and cannot rise from a sitting

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

position without the aid of a stick or by pulling on a chair. This weakness in the legs increases until there is a paralysis of the muscles. This is especially marked in the leg below the knee, and the toes or foot cannot be moved voluntarily. There is usually shortness of breath upon slight exertion, and throbbing in the chest is marked and easily visible in the advanced stages of the disease.

In the last stages of the disease there is a marked difficulty in breathing, the breathing being very rapid, and the throbbing over the heart being very noticeable. The urine is usually not affected until the last stages, when it becomes very scanty. This is usually just before death.

Wet Beriberi.—The symptoms of this form of the disease may be so vastly different from the dry form that an inexperienced observer would not recognise them as being the same disease. The most marked symptom is swelling. This may begin in the feet and extend to the whole of the body. The legs and abdomen, face and arms may be bloated to twice the normal size, and the patient be unable to move because of the great weight of his body. The tingling and pains that are so characteristic of the dry form of beriberi may be entirely absent in this form, or they may be very mild and give no trouble to the patient. The heart may be affected so that the breathing is very rapid and short. The urine may be less in amount than usual.

Progress of the Disease.

In either form of this disease the progress may cease at any point and gradually improve; or what is more common, the disease will cease to progress and remain at the same stage, neither improving nor getting worse for some time. In the dry form it may become chronic in nature, and then the muscles of the legs waste away until the calf muscles are no larger than the ankles. The arms may also be wasted, and the patient be little more than a skeleton. The condition may change from one form to the other, i.e., the swelling may all disappear and be followed by wasting and paralysis; or the wasting may be followed by great swelling of the body.

Treatment.

I have followed the outline of treatment given below, and find that cases respond in about six to ten days' time. It is usually this length of time before there is any appreciable improvement in the symptoms, but as soon as improvement begins the symptoms rapidly improve. In the mild cases the patient may be entirely well in ten days. In the severe cases, where difficult breathing and paralysis occur, it may take one and a half to two months' treatment in order to effect a cure, and some of the tingling and pulling in the legs may last for three or more months, but usually six weeks will see all the symptoms disappear. The order of improvement may be expected to be as follows:—The tingling gradually becomes less and then the pains begin to lessen. The pain and burning in the abdomen disappear and the patient becomes quite comfortable. If there has been much difficult breathing, that will gradually lessen, and the swelling over the shins disappears. The pulling in the legs and the tightness in the abdomen are the last to pass away.

Treatment—Prophylactic or Preventive.—This is the most important. In places where beriberi is common, and where rice is the main article of diet, the people should be instructed to take more vegetables and fresh fruits, and to take a smaller quantity of chilli in their curry. I believe that the chilli kills the vitamines in the vegetables. All rice should be of the red or unmilled variety, and in addition some food product should be given to augment the vitamine content of the red rice. Marmite, a commercial extract of yeast, is recommended on p. 360 of Manson's *Tropical Diseases* as a prophylactic for beriberi, and I have used Marmite successfully for this purpose.

Treatment—Medical.—I give every patient Marmite. Patients are instructed to take a quarter of a teaspoonful (twenty grains) of Marmite every morning and evening, or, if they can afford it, three times a day. They mix it with a little water, and take it as medicine, or they spread it on bread, or mix it with their rice or *dhâl*. I do not allow them to mix it in curry, for I believe the vitamines would be destroyed in this way. Each patient within walking distance of the hospital is told to come each day for some rice bran infusion (tea). If they cannot come or send someone, they are instructed to make the rice bran tea as follows:—Take rice bran (rice polishings from the mill) sufficient to fill the hollow of the hand, heaped up, and add it to a half glass of cold water, and let it set overnight. In the morning strain the rice bran tea through a thin cloth, and take half of it then, and the other half at night. This must be made fresh daily as it sours very quickly. The rice bran tea can be sweetened with sugar if desired.

The patients who can afford it are put on to a vegetable diet, and are not allowed any rice whatever. They are given ground wheat twice a day as a cereal. They are urged to take fruit juices, and if they have no scruples against it, they are urged to eat eggs. The poor are allowed only red rice, and are not permitted to take any white rice at all. They cannot afford to take more vegetables, milk, or eggs, but they get along almost as well as those who can afford a better diet.

If there is any difficult breathing the patient should be confined to bed, and it is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

better to change the sleeping room if possible. There should be plenty of fresh air, and the room should be clean and light. Massage of the limbs in the paralytic cases is of value after the pains and tenderness have gone.

SUPPURATION OF THE MIDDLE EAR: ITS CAUSES, SYMPTOMS, DIAGNOSIS AND TREATMENT.

By A. N. PALIT, F.R.C.S. (Edin.).

MAJOR, I.M.S.,

Civil Surgeon, Monghyr. Formerly Clinical Assistant, Neumann and Hajêk Clinics for Diseases of the Ear, Nose and Throat, Vienna.

ACUTE OTITIS.

AURAL suppuration, a very common condition, is the cause of an immense amount of ill health, disability and quite a considerable mortality. Statistical returns being what they are, deaths from the above cause are seldom returned as such in this country. The condition is readily curable by simple treatment in the early stages of acute otitis; hence the treatment of acute suppurative otitis is much more important than that of chronic otitis. When the disease has been allowed to run a chronic course, it becomes very obstinate and treatment is much more difficult. Even if the otitis be cured, a chronic adhesive process may be set up leading to progressive deafness.

For this reason every case of earache or of a child putting its hand continually to the ear and every case of unexplained pyrexia in a child should be carefully investigated, and the ear as well as the throat examined. A forehead mirror, different sizes of ear speculums (six would be ample) and a bright light are essential for this examination. A petrol lantern or even a kerosine reflector lamp is all that is required. Brunton's auroscope or electric auroscopes are not recommended.

I regret to have to observe that this branch of surgery is very little understood by the medical profession in this country, and ideas about the ear, nose, tonsils or adenoids appear to be vague. In this article details of special or difficult methods of treatment will not be discussed, and an effort will be made to standardise treatment as far as possible.

ACUTE OTITIS MEDIA.

Causes.—Any cause which facilitates the entry of organisms into the Eustachian tube and tympanic cavity and by obstructing the orifice favours their retention, predisposes to otitis media. Thus adenoids are the commonest predisposing cause. Amongst others are new growths in the naso-pharynx, suppuration of any of the accessory sinuses of the nose, a deviated septum, enlarged hypertrophied posterior tips of the inferior turbinals, etc.

The disease is a frequent accompaniment of the acute infective fevers such as scarlet fever, measles, influenza, or even of a common cold. It may occur after traumatic rupture of the tympanic membrane especially if neglected, or as a result of faulty technique in removing a foreign body from the external meatus. It may follow improper use of nasal douches or occur after an operation on the naso-pharynx such as removal of adenoids. Sea bathing and diving may bring on an attack.

Bacteriology.—The organisms most frequently found in acute otitis are the streptococci; *Micrococcus catarrhalis* or pneumococci are sometimes found. It is important to remember that acute otitis is a mono-bacterial infection and the organisms are found in pure culture. Staphylococci are never found in the beginning; they often constitute a secondary infection.

Streptococcus mucosus, a capsulated organism, is sometimes responsible for a very malignant variety of otitis. This variety of otitis will be described later.

Pathology.—In the early stages the inflammation is confined to the mucous membrane of the tympanum, and as a rule the mucous lining of the antrum and cells are also inflamed. The tympanic membrane next undergoes necrosis at one point and perforates. Pus escapes and under suitable conditions the ear heals perfectly. But more often secondary infection supervenes, the mono-bacterial becomes a poly-bacterial infection and the disease becomes a chronic one. The bones beneath the thin mucosa may undergo necrosis. If mastoid suppuration supervenes, the greater part of the mastoid may be necrosed and the infection may spread to the meninges and brain, to the lateral sinus, to the neck, to the labyrinth and facial nerve, etc.

Symptoms and Treatment.—Acute otitis may be conveniently divided into three stages:—

First stage.—The onset of pain is generally sudden, rapidly becoming severe. The pain is described as piercing, boring, or throbbing, radiating over the side of the head. The temperature ranges from 100° to 103°F. and in children may be 105°F. There is deafness, often pronounced, tinnitus or even vertigo. In adults, however, sometimes there may not be much pain or constitutional disturbance. In children symptoms are always much more severe. There is marked constitutional disturbance and the case may even simulate meningitis; restlessness and sleeplessness are marked and as physical examination is difficult, one has often to diagnose by symptoms alone.

The tympanic membrane is red, redness being most marked round the handle of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

malleus and in Shrapnell's membrane. The short process of the malleus is still visible.

Treatment.—The point that should be always borne in mind in treating ear conditions is that the tympanic membrane is a highly sensitive structure and all manipulations should be gentle.

The ear should be cleaned of cerumen and debris, either by gentle syringing with warm 1 in 60 carbolic lotion or with cotton-wool swabs either dry or wrung out of alcohol. Instil half a teaspoonful of warm 5 per cent. carbolic glycerine, after which plug the external ear lightly with cotton-wool. After this, dry hot fomentations, with a hot salt or hot sand bag or a hot water bag should be applied. The patient may sleep on a hot water bag covered with flannel.

Carbolic glycerine 5 to 10 per cent. is a most excellent remedy—it renders the ear aseptic, relieves pain and causes dehydration. A couple of leeches, real or artificial, over the mastoid process gives immediate relief.

Second stage.—The whole of the membrane is red, velvety, swollen, and bulging, and covered with small white spots of desquamated epithelium. The landmarks, i.e., the handle and the short process, are no longer visible. At first the exudate behind the membrane is serous, and there may be some exudate in the external meatus as well although there is no perforation. This is an important point to remember, as when there is an exudate in the external ear one is liable to jump to the conclusion that there must be a perforation. When the secretion becomes purulent the colour of the drum becomes yellowish.

Treatment.—Immediate paracentesis or myringotomy. Sterilize the pinna and external ear with absolute alcohol or biniodide and spirit lotion. Take a myringotome, an old cataract knife held between the thumb and index finger, or even a big Hagedorn's needle held in a needle holder; pass the instrument through the speculum, and under inspection

the point is thrust into the most prominent bulging part of the drum, and the incision is prolonged up or downward as the case may be. The incision must be free, otherwise it will close up very soon, often after 24 hours.

It does not much matter where the membrane is incised so long as the handle is not injured, and the incision may be made either in front of or behind the handle, but very often the best drainage is obtained by incising behind. An anæsthetic is not necessary though most English text-books recommend a general anæsthetic.

Instil 5 per cent. carbolic glycerine after the blood and pus are wiped out and insert a thin gauze drain through the incision. Hot fomentations should be continued as before. The patient feels instant relief after this operation.

The gauze should be changed every 4 to 6 hours if possible, but in any case it must be changed after 24 hours but should not be re-inserted through the incision. If the wound heals before symptoms disappear, it may be necessary to do a paracentesis again.

These incisions heal rapidly, leaving a thin white scar. If the drum is incised even before there is suppuration no harm is done, whereas if the drum be left to perforate of itself it takes much longer to heal and the disease may become a chronic one. So the golden rule is, even when in doubt operate. Pus is seldom profuse after myringotomy. As a rule there is just a streak of pus in the hæmorrhage that follows. Syringing is better avoided at this stage.

Third stage.—The drum gives way and perforates. The discharge which is at first thick and purulent becomes muco-purulent. At this stage there is little or no pain, but the patient complains of deafness, feeling of fullness, noises and pulsation in the ear. The discharge lasts for about a month, after which, under favourable conditions, it may dry up. The perforation may close but deafness, fullness, the noises in the ear persist. On examination the perforation may not be always visible but a pulsating collection of fluid at the lower margin of the drum is pathognomonic. If still doubtful inflation may be tried—a hissing sound would be heard in case of perforation—or the patient may be told to close his mouth, pinch his nose, and then blow. Fluid and bubbles would be seen coming through the perforation.

Treatment.—It is at this stage that the mono-bacterial becomes a poly-bacterial infection and the acute otitis tends to pass into a chronic one. If the discharge be slight do not syringe the ear. Clean the ear with cotton-wool swabs soaked in alcohol or hydrogen peroxide. Then fill the ear with hydrogen peroxide, let it bubble, then dry the ear, and pour in 10 drops of boric alcohol (gr. viii to gr. xv in one ounce of alcohol, 70 per cent.); then insert a light cotton-wool plug or preferably a small piece of sterile gauze. If the discharge be profuse or foul the ear should be syringed through a Hartmann's

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cannula. The cannula is attached by means of rubber tubing to a metal ear syringe.

This is a safe way of syringing the ear. If this instrument is not available, an ordinary ear syringe may be used, but the fluid should be directed to impinge on the superior or postero-superior wall of the external meatus and not on the drum. Force should never be used.

The fluid will then scour the surface and inferior angle of the drum and will not get into the tympanum. This point should always be remembered while syringing the ear. After syringing, the ear should be treated with hydrogen peroxide and alcohol as described before. Care should be taken to prevent external otitis by touching the external meatus every other day with 5 per cent. silver nitrate solution and then covering the surface with sterile vaseline. If pain and temperature persist for more than two weeks after myringotomy or perforation, and if there is tenderness over the mastoid, the antrum and cells should be opened and drained. But I cannot advise all and sundry to undertake this operation—doubtless it is a simple operation, but still it must be performed by a trained surgeon.

If the discharge persists and if there is no obvious obstruction at the Eustachian orifice, inflation should be tried. The simplest way to use the Politzer bag is as follows:—

Make the patient take a mouthful of water. Insert the vulcanite piece, protected with cotton-wool or rubber tubing, to that side of the nose, the ear on which side it is intended to inflate, i.e., to the right side of the nose if the right ear is to be inflated. Ask the patient to swallow, and as he does so press the bag. Politzerisation should not be done oftener than thrice a week.

After the acute symptoms subside any predisposing cause such as adenoids must be removed. Many of my young patients' ears heal without any further treatment once the adenoids and tonsils are removed. The parents seem to have an idea that once the child has been operated on further treatment is superfluous, so they are not brought to my clinic any more, but occasionally I get hold of some of my old patients and find the ear more or less normal.

Diagnosis:—From furunculosis. In this disease the external meatus, pinna, and the skin covering the mastoid may be red and œdematous and one is liable to diagnose acute otitis. The furuncle generally occludes the external meatus and the drum is not visible. In eczema there may be a serous exudate, but the external meatal wall is covered with crusts and alcohol causes severe burning. Both in furuncle and eczema manipulations of the pinna are painful, and gentle tapping of the tip of the tragus with the tip of the index finger causes intolerable pain. This is pathognomonic.

In conclusion I wish to impress on my readers that a velvety red bulging drum must be incised. You will never regret doing so, and you will save a lot of suffering and chronic ill health and at least some lives. If you make a mistake and find no pus, you need not be ashamed; you have done no harm, on the contrary you have very probably done a lot of good. The case will resolve quicker. Do not be disappointed if you do not see much pus—it is generally just a streak in the blood. Paracentesis is even more often indicated in children than in adults, so even when in doubt incise. The operation is practically without danger—but remember to have the head held firmly, otherwise the labyrinth may be injured.

Cases of acute otitis seldom come to the specialist; the general practitioner is the person who treats them and he can do an immense lot of good by recognising the disease and treating it properly at the early stages.

I shall describe one illustrative case to show the excellent results of paracentesis:—

A young Hindu, male, aged 20 years, came to my ear clinic on a Monday. Acute otitis was diagnosed, but as it was one of my very busy days I asked the man to come on the following day. Glycerine carbolic drops and fomentations were ordered. The man did not come on the following day. On Wednesday I was asked to see a case of pneumonia. The patient was delirious and had a temperature of 105°F. His face was very red and flushed. There was only a small patch in front of the lower lobe of the right lung, and some diminution of breath sounds around this area. There was nothing to make one suspect any ear trouble. On Thursday the temperature was still 105°F., the head

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was retracted and there was twitching of the fingers. The threatened meningitis made me look at his ears and the right drum was found to be intensely red and bulging. It was then that I recognised my patient of Monday before. Paracentesis was performed within an hour, and the temperature was 101°F. on Friday morning and normal by Saturday. I saw the patient a month later; the drum was perfectly healed. The patient complained of a feeling of fullness and heaviness in the ear. Catheterization of the Eustachian tube and inflation put this right also. But for timely paracentesis the patient would most probably have died either of meningitis or pneumonia.

MUCOUS OTITIS.

This is caused by the *Streptococcus mucosus*, a capsulated coccus, and may be described as a sub-acute but virulent form of otitis. The symptoms are slight pain, slight discharge which is not always present, as it dries up now and again; poor hearing, not improved by inflation; the drum is greyish-red, thickened, no longer translucent, the details are visible but vague. The disease gives rise to formation of a soft variety of connective tissue which fills the tympanic cavity and antrum and permeates the cells and causes wide destruction of bone. Unless eradicated in time by a thorough radical mastoid operation the disease pursues its relentless course and the patient eventually dies of some intracranial complication.

CHRONIC OTITIS.

In most cases chronic otitis supervenes upon acute otitis because of the persistence of the predisposing cause and perhaps also as a result of the mono-microbic becoming a poly-microbic infection. Hence the importance of keeping the external meatus clean and aseptic before the drum perforates or before paracentesis is done. Sometimes the disease is chronic from the outset, as in tubercular otitis or in cases in which, owing to a developmental defect, remains of the jelly-like substance filling the tympanic cavity of the fœtus persist and give rise to a chronic otitis. Cholesteatoma may be primary (Ruttin) and may start as a chronic otitis, but in most cases the condition is secondary to a marginal perforation. As already stated the mucous lining is at first affected in suppurative otitis, later infection spreads to the ossicles and bony wall. Of the ossicles the incus is the one most often affected. Granulations and polypi appear and the tympanum becomes honeycombed with pus-secreting cavities. Infection spreads to the antrum and mastoid cells, may spread to the labyrinth, to the meninges and brain, to the lateral sinus. The facial nerve may be affected in several ways. The mastoid abscess may open into the tissues of the neck, giving rise to von Bezold's abscess. The perforation of course persists or even enlarges.

The *symptom* for which the patient seeks advice is either (*a*) loss of hearing, which may be slight or in the old cases may be very great, or (*b*) discharge from the ear, which is variable. It may be profuse or scanty, it may be foul smelling. Often the patient has dry periods when there is no discharge, alternating with periods when there is much discharge and a certain amount of pain as well. Sudden stoppage of the discharge is always a danger signal and may be followed by intracranial complications. Other signs are vertigo, tinnitus, headache, etc.

Examination of the Ear.—The practitioner should be familiar with the normal appearance of the tympanic membrane. Pus, crusts, epithelial debris, cerumen must be removed by means of cotton-wool swabs held with a pair of aural forceps. If the meatus is full of foul discharge it should be syringed, but never syringe a ear with a dry perforation. Cerumen is best removed by first soaking in sterile olive oil, carbolic glycerine, or hydrogen peroxide, and then syringing.

During examination of an ear the following points should be noted:—

Condition of the external meatus: presence of eczema, sinking of the roof and postero-superior wall of the bony meatus, which means antrum suppuration.

The membrana tympani.—First determine whether it is present or absent; this may sound ridiculous but it is a fact that even otologists cannot make up their mind on this point after inspection alone. Next note its colour, landmarks, and general appearance. Note the presence or absence of granulations and polypi. Lastly, carefully examine the perforation, noting its size, shape, situation, edges, whether single or multiple. A perforation may be hidden by polypi.

Perforations may be classified according to their position:—

(*i*) If situated in front of the handle of the malleus the perforation is due to Eustachian tube suppuration. These cases though harmless are very obstinate and are liable to recurrence even if they heal up.

(*ii*) If large and kidney-shaped and situated below the handle, it is known as meso-tympanic, and this type is the easiest of all to cure. Prognosis is good.

(*iii*) A small perforation in Shrapnell's membrane is known as attic perforation. It means threatened intracranial complications or cholesteatoma.

(*iv*) A perforation in the postero-superior quadrant often means antrum suppuration. The whole of the posterior part, together with the antral wall, may be destroyed.

(*v*) A small central perforation very often ends in an intracranial complication, especially sinus thrombosis (Neumann).

(*vi*) A marginal perforation is often a sign of cholesteatoma.

(*vii*) More than one perforation, especially if small, often indicates tubercular disease.

Treatment.—In uncomplicated cases the following routine treatment will suffice. Clean the ear with cotton-wool swabs soaked in alcohol or hydrogen peroxide. Then pour about half a teaspoonful of hydrogen peroxide into the ear while the head is so held that the affected ear points upwards. Let the hydrogen peroxide bubble, and when bubbling ceases pour out the fluid. Dry the ear with cotton-wool, and pour in 10 minims of boric alcohol (boric acid gr. x to xv to 70 per cent. alcohol, 1 oz.). If this causes smarting use alcohol diluted with an equal part of distilled water.

If the discharge is profuse or foul, syringe before the hydrogen peroxide and boric alcohol is instilled. One should however bear in mind that too much syringing is bad, and many cases start healing as soon as syringing is stopped. Considerable patience is needed in the treatment of these cases, and treatment may have to be continued for a year or more before healing occurs. Granulations should be touched with a 10 to 25 per cent. solution of silver nitrate or with trichloracetic acid fused on a probe. Polypi have to be removed with an aural snare or a pair of forceps.

The predisposing cause should be determined. Thus in children adenoids and tonsils have often to be removed. Scraping the surface of the adenoids or cutting a section of the tonsils is worse than useless. The whole bunch of adenoids should be removed and the tonsils enucleated. For this the patient should be sent to one of the ear, nose and throat clinics.

In adults septic conditions in the nose and naso-pharnx should be treated. The commonest conditions are suppuration of one of the accessory sinuses; nasal polypi; deviated septum; enlarged posterior tips and remains of adenoid growths, or even septic tonsils. Even when a cure is not expected hydrogen peroxide and alcohol treatment will prevent recurrent attacks of acute exacerbations and often prevent further damage. Politzerisation once or twice a week drives out accumulated discharges in the tube and tympanum.

Suppuration of the antrum is the commonest complication of otitis and very often the middle ear cannot heal on account of this.

Indications for, and a description of, the radical and conservative mastoid operations hardly come under the scope of this article and need not be discussed here.

CHOLESTEATOMA.

This is a chronic but rather a malignant variety of chronic otitis. A cholesteatoma is an overgrowth of epidermal tissue which passes inside into the tympanic cavity through a marginal perforation. The growth continues, invading the antrum, cells, Haversian canals in the bone, and finally produces intracranial complications. The discharge is very foul. The ear is full of whitish, cheesy matter and in the later stages the destruction of bone may be extensive. In one case that came under my treatment there was a large cavity behind the ear, the size of which was bigger than that of a golf ball. The lateral sinus, the dura covering the temporo-sphenoidal lobe and the cerebellum were exposed. These patients should be operated on before it is too late.

A Mirror of Hospital Practice.

A CASE OF FIBRONEUROMA OF THE CAUDA EQUINA.

By FRANCIS CHRISTIAN, M.R.C.S., L.R.C.P. L.M.,
Surgeon, Vajira Hospital, Bangkok.

TUMOURS of the cauda equina are so exceptional that I think the case of a boy that passed through my hands merits publication.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Seng, a Siamese boy of 6 years was admitted to the Vajira Hospital, Bangkok, in May 1925. The parents gave the following history. The boy was normal until he was over two years old, when for the first time they noticed that he was losing control over the bladder and rectum. Slowly this became more marked and it was obvious to them that he was quite insensitive as to the escape of urine and fæces. This incontinence became more pronounced as he grew older. About the same time they noticed a slight rounded prominence in the middle line above the level of the upper end of the sacrum about the size of a small cherry, which gradually grew, and at the time of admission it was as big as a small hen's egg cut longitudinally in half, the broader end being below.

His left leg was slightly weaker and half to three-quarters of an inch smaller in girth than the right leg. The muscles were not so well developed in the left leg. It was difficult to mark out the areas of loss of epicritic and protopathic sensation, but apparently these were diminished on the posterior aspect of the left thigh, and superficial pain also was diminished in the same area. There was pain on pressure over the left sciatic nerve. The distribution of pain and sensory disturbance could not be marked out definitely owing to the child getting into a fright on the mere approach of any of the responsible members of the staff. The mucous membranes of the urethra and rectum were insensitive. The swelling did not appear to become appreciably tenser when the child cried.

The condition was diagnosed as a case of meningo-myelocele with possible involvement of the cauda equina and certain sacral roots.

Operation.—An incision was made over the tumour along the middle line, and on cutting deeper the bulk of the tumour was found to consist of a firm thick layer of fat, whilst the sac itself was very small indeed compared with the size of the tumour. There was a lozenge-shaped space between the spines of the last two lumbar and the first sacral vertebræ through which the spinal meninges protruded a little. On opening the sac a slight dilatation of the spinal canal was seen in the area and the laminæ of the vertebræ mentioned above were somewhat defective at this level. There was some escape of cerebro-spinal fluid which was controlled with difficulty, and on clearing the field the leech-shaped tumour of the cauda equina, with its head below and gradually tapering upwards, came into view in addition to five nerve filaments, three on the right and two on the left of the tumour. The head of the tumour which was quite hard was found attached to the lower part of the sac, but the body was freely movable in the subdural space and the tail was attached above. The tumour was freed from its lower attachment first and on pulling it down the tail end was found fixed to the dura, in addition to its attachment above, as well as to some nerve filaments, and it was then separated from its attachments. The five nerve filaments were attached to the sac by their lower ends, and these were freed and kept out of the way before the main tumour was dealt with after partial laminectomy. After cutting away the redundant portion of the sac, the dural opening was closed by one continuous suture of very fine catgut. The wound was then closed after excising the excessive fat and no drainage employed. Firm bandages were applied over pads of wool without a splint.

After-History.—There was no evidence of the child suffering from much shock after the operation, which lasted forty-eight minutes. It was practically impossible to keep the parts clean owing to the incontinence of urine and fæces, and as a result, the superficial part of the wound got infected in the lower end where a little pus formed. There was some rise of temperature on the fifth day, but in a couple of days the wound became free from pus and thenceforward progress was uninterrupted. There was no escape of cerebrospinal fluid, and the stitches were removed on the tenth day. On the 28th day after the operation the child for the first time said that he knew when he was passing urine and fæces and from this time onwards the improvement was rapid, and he regained partial control over the bladder and rectum about six weeks after operation. Three months after, the sphincters acted quite in the normal way. The difference in the size of the leg slowly disappeared and there is no evidence of any weakness of the left leg.

Pathology.—The tumour was kindly examined by Dr. A. G. Ellis, Professor of Pathology, Medical College, Bangkok, to whom I desire to express my thanks for his permission to include in this letter his report, which is as follows:— The specimen is a mass of tissue 2 cm. long; slightly more than half of this is smooth, soft, red in colour, almost cylindrical in shape, and 0.6 cm. in diameter. The remainder is 0.8 cm. in diameter, has a rougher surface, is grey in colour, and fairly firm. Incision shows that the cylindrical part extends through most of the grey portion, the latter surrounding and distorting it. Sections of the smooth end of the specimen are partly of somewhat atypical white matter of a spinal cord. This is arranged as two lateral portions widely separated by fairly dense fibrous tissue containing scattered nerve fibres. These project like cornua and are partly bordered by thin membrane-like pia mater. The remainder of this part is partly neuroglia and cells but contains many small blood vessels, resembling a glioma more than it does spinal cord.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Sections through the large end of the specimen are chiefly of dense fibrous tissue in irregular bundles containing numerous nerve fibres. Among these are scattered areas of spinal or neurogliar tissue like that of the upper end. Diagnosis—pathological—a fibroneuromatous new growth containing gliomatous tissue.

A CASE OF CEREBRAL ABSCESS FOLLOWING OTORRHŒA.

By MATI LAL DAS GUPTA,

Sub-Assistant Surgeon, Jail Hospital, Barisal.

RAMJAN ALI, an old man of 55 years, was admitted to this hospital on the 27th June 1926, suffering from otorrhœa on the right side, with fever, and a temperature of 103°F. tion continued the whole day; the temperature went up to 103°F., and the patient died at 5 p.m.

Autopsy.—On post-mortem examination the right side of the brain below the Rolandic area was found to be congested and a big cerebral abscess was found below the surface in this area.

A special feature of this case was that the patient had never shewn symptoms of cerebral irritation until the 20th June when symptoms suddenly set in. Had he complained of severe headache, or had he shewn any suspicious symptom, one would have trephined. The injections of iodine intravenously appeared to be curing the condition, but the onset of suppuration in the brain appeared without any previous warning.

The discharge from the ear was very offensive, and his bowels were constipated, though they moved after an enema. In two or three days' time he was better and the discharge was much reduced, but he again got high fever on the 1st July, and this time the fever was of a hectic character. On the 12th July he was given an intravenous injection of tincture of iodine (1 c.c. in 10 c.c. of distilled water), and the fever came down the next day, but then again rose to 102°F. He was given a further injection of the same dose on the 14th. By the 18th the temperature had dropped to normal and he seemed to be progressing satisfactorily. On the 20th, however, he vomited several times and suddenly became unconscious. The temperature shot up to 101°F., his left extremities became paralysed, and also the right side of his face. This condi-

I am much indebted to Rai J. N. Mittra Bahadur, Civil Surgeon, Bakargunj, for his kind permission to publish the notes on this case.

A CASE OF GENITAL ATRESIA.

By K. KOCHUNNI MENON, L.M.P.,

Sub-Assistant Surgeon, Anthikaeb Dispensary, Cochin.

A *pulaya* girl, Kotha by name, aged 18 years, was brought to me at this dispensary on the 29th July, 1926 by her parents with a history of difficulty in micturition and backache. She looked sick and distressed and could only walk with difficulty. Enquiry elicited the statement that she had never menstruated. My female compounder, who

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

carried out an examination of the patient, reported that the vulva was occupied by a projecting fleshy mass.

I examined the patient and found that the case was one of genital atresia. A cyst-like mass was found bulging externally from the vulva, its septum thick and tensely drawn to the lateral edges of the vulvo-vaginal entrance. A small spot a little above the centre of the septum appeared to be quite thin, shining, and smooth. The transverse diameter of the septum was some 1¾ inches.

Operation.—An enema was given and the parts cleaned. An exploratory puncture was made with a needle in the centre of the thinned-out membranous patch and settled the diagnosis, for immediately about a pint and a half of dark venous blood and glairy fluid gushed out, together with a profuse flow of urine from the bladder. The incision was widened and the vagina well douched with lysol lotion. I then introduced my fingers and explored for the uterus. To my surprise, I found none. After making repeated and vain attempts to find the uterus, I packed the vagina with iodoform gauze, and sent the patient back to bed in her own cottage—there being no in-patient accommodation available at the dispensary.

Four days later the patient returned for examination, and walked to the dispensary. After douching, I again tried to find the uterus, but failed to do so. Not having a vaginal speculum available, I used a rectal speculum, and with the aid of a pocket electric lamp examined the parts. No sign of any os uteri was visible; all that was visible being a few tiny pin-point reddish spots in the vagina, apparently due to the retained menstrual discharge.

In such a case, where does the menstrual fluid come from? Is menstruation possible in the absence of the uterus, or in the absence of any communicating canal from it to the vagina? The only explanation that I can offer is that, owing to the great distension of the vagina from the retained menstrual fluids and the distended bladder, the cervix may have been completely taken up by the vaginal walls, and the uterus pushed down into Douglas' pouch, so that a tiny posteriorly-situated os uteri was invisible. I asked the patient to return for further examinations later, when conditions should have become more normal, but she unfortunately did not do so.

The interest of the case lies—not so much in the imperforate hymen, which is a condition frequently encountered in medical practice in the tropics—but in the complete failure to find any sign of a uterus. Readers of your journal may possibly be able to supply some information on this point.

(*Note.*—Cases of imperforate hymen are of such frequent occurrence in India that scarcely a month passes without our receiving one or more reports of the occurrence of this condition. The interest of Dr. Menon's case, however, lies in the *age* of the patient. Atresia of the genital canal in these cases may occur at the hymen,—the usual situation,—at the os uteri, or between the cervix uteri and the cavity of the body of the uterus—the latter two situations being unusual. Should the obstruction persist for some years after puberty, actual atrophy of the uterus may occur, the thinned-out and atrophied uterus lying as an imperceptible organ upon the top of the ballooned vagina or cervix. The condition present in Dr. Menon's case appears to illustrate this point. It would be very interesting if the subsequent history of this patient in after-years could be traced. —ASSIST. ED., *I. M. G.*)

A CASE OF ACUTE GLOSSITIS.

By A. BAYLEY DE CASTRO,

Junior Medical Officer, Port Blair.

IN the *Indian Medical Gazette* for September 1926, a case of acute glossitis was recorded by Dr. G. S. Chawla of Lahore, and as I had a similar case in May of this year, and as such cases are not common, I am sending in these few notes.

Magha Lall, a Hindu boy of about 16 years, was brought to hospital on the morning of the 7th May 1926, with his tongue enormously swollen. The history was that this condition had started insidiously the previous night. So enormously swollen was the tongue that the boy could not completely close his mouth, and it was impossible to see the back of his throat. Respiration was carried on through the nose, and was 26 per minute, while the pulse ranged between 96 to 100 and the temperature was 100°F. The patient had very dirty teeth. An acute streptococcal infection was feared. There was a good deal of salivation. In spite all this, however, the patient did not appear to be greatly distressed.

He was given a brisk purge, a hot antiseptic gargle frequently, and externally a spongiopiline fomentation was applied.

There was a lot of relief by the morning of the 8th, and by the morning of the 9th the swelling of the tongue was so much reduced that a proper examination of the inside of the mouth was possible. It was then discovered that about the middle of the right side of the tongue there was a small ulcer, caused most probably by the friction from a jagged carious tooth.

There is nothing further to record, but one salient feature should be remembered, i.e., the sudden onset in these cases.

PHARMASOLS

REGD.

THE MOST EFFICIENT COLLOIDS

Truly scientific, active, reliable, economical, stable, Colloidal preparations of standard drugs for medicinal use.

Pharmasols REGD

CALCIUM

The one line of endeavour in the treatment of **TUBERCULOSIS.**

Pharmasols REGD

SULPHUR

A well-known specific in Subacute and Chronic Rheumatic Affections.

Pharmasols REGD

IODINE

The ideal form of Iodine treatment in Pneumonias, Influenza Plague, etc.

Pharmasols REGD

TRIMINE

Remarkably useful in Eczemas and Obstinate Skin Diseases.

Pharmasols REGD

MANGANESE

May safely be termed a true specific in all Staphylococcic and Streptococcic infections and its field of usefulness is therefore very extensive.

Pharmasols REGD

FERRO-MALT CO.

Is of unquestionable value in Anæmias, Rickets and Rundown Conditions.

Don't use other Colloids until you have seen and tried Pharmasols. They are recognized as being completely in advance of everything else in the Colloidal line and these new improved Pharmasols are without a rival in quality and low prices to-day. The word Pharmasols is your guarantee that these Colloids are of immense popularity throughout India, Burma and Ceylon, unsurpassed for reliability, economy, and stability, because the methods of manufacture of these Colloids are totally different from all other so-called Colloidal preparations offered for sale in this country. Those Doctors use them who most seriously want low prices and guaranteed results. Always insist on Pharmasols.

All in Boxes of 6 Ampoules.

SODIUM IODIDE A.F.D.

In Infections and Allergies.

Each ampoule of 20 c.c. contains: Sodium Iodide 2 gms. (31 grains).

Splendid results have been obtained with this preparation, in a number of cases including Hay Fever, Rheumatism, Gout, Arthritis, Arteriosclerosis, etc.

In Asthma, the brilliant immediate results that follow these injections are marvellous and patients get an almost miraculous measure of relief.

In boxes of 6 ampoules of 20 c.c.

ORARGOL

Injected in time and in suitable dosage, ORARGOL is capable of cutting short every serious case of PNEUMONIA, INFLUENZA, ERYSIPELAS. It is the ideal remedy in all chronic inflammations of the mucous membranes and the most efficient substitute for COLLOIDAL SILVER.

ENCEPHALITIS LETHARGICA.

An Interesting Report:—

"A case of Encephalitis Lethargica of severe type, treated successfully by injections of Electro-Colloidal Gold and Silver." (Orargol)

— *The Lancet*, July 24th, 1926, p. 172.

ORARGOL AMPOULES, 5 c.c. and 10 c.c. Acute and Chronic Infectious Conditions (Septicæmia, Pneumonia, Influenza, etc.).

ORARGOL (in bulk) . . Internal and External Antisepsis (Intestinal Intoxication, Wounds, etc.).

BENZO-BISMUTH A.F.D.

THE ONLY ONE SOLUBLE, STABLE, NON-TOXIC BISMUTHIC ORGANIC SALT, OF HIGH SPIROCHÆTICIDAL POWER THAT DOES NOT CAUSE BISMUTHIC POISONING WHICH ADMINISTERED BY INTRAMUSCULAR INJECTION IS PAINLESS AND IN MANY RESPECTS SUPERIOR AND CHEAPER TO OTHER BISMUTHIC PREPARATIONS USED IN THE CURE OF SYPHILIS.

MAIN ADVANTAGES

(1) The small quantity that is injected, not exceeding 1·5 c.c.
(2) The ease with which the drug is administered either intramuscularly or subcutaneously.
(3) The painlessness after injection.
(4) The uniformity of dosage.
(5) The comparative cheapness.
(6) No liability to toxic symptoms.
(7) Complete solubility of the drug in a watery medium without leaving any particles in suspension.

In Benzo-Bismuth A.F.D the Physician has an extremely active weapon, easily handled, without danger, without risks and with the minimum of inconveniences, capable of giving results as marvellous as those previously obtained only with arsenic.

(Presented in box of 5 ampoules of Benzo-Bismuth A.F.D.)
(accompanied by 5 tubes of Distilled Water.)

QUINARSINE A.F.D.

A very active specific against Malaria, and a regular treatment which will result in the cure of the disease, and the rapid disappearance of gametes from the blood.

In ampoules and pills.

BLENACROL A.F.D.

A very powerful Antiseptic, non-caustic, non-toxic, for urethral injections in the treatment of GONORRHOEA and its complications.

In bottles containing about 3 ozs.

Indian Medical Gazette.

JANUARY.

THE FUTURE OF MALARIA CONTROL IN INDIA.

THE year 1927 is likely to prove of considerable importance in connection with the study and prevention of malaria in India.

. . . . . .

In January 1927, India will have the honour of welcoming Sir Ronald Ross, and a tablet is to be unveiled at the small laboratory in the grounds of the Presidency General Hospital, Calcutta, where he made his ever-memorable discovery. The story of Ross' great discovery has often been told, but—as it is perhaps unfamiliar to the present generation of medical men in India—we may perhaps be excused for again giving an outline of his work.

In the year 1895, Sir Ronald Ross—at that time Surgeon-Major Ross of the Indian Medical Service—determined to discover how malaria was transmitted from man to man. The conditions under which Ross worked are to-day almost incredible to the medical research worker in India. The story is fully told in his *Memoirs*, a volume which every worker imbued with the spirit of discovery should read. It is true that there had been great pioneers of medical research in India prior to Ross' day—D. D. Cunningham, Vandyke Carter and Timothy Lewis, to name but three; but in 1895 a military medical officer who was keen on research work was regarded as a somewhat unpleasant phenomenon—polo and pig-sticking being far more important. To-day, thanks to the re-organisation of the Indian Medical Research Department by the late Sir Pardey Lukis, conditions are utterly different; the problems are there, there is financial provision for their investigation, the only difficulty is to find men of the right type to investigate them; conditions such as were present in Ross' day can never recur.

Ross had been on furlough to England in 1894, where he came under the spell of the late Sir Patrick Manson, at that time Dr. Manson, who had retired from practice in China, and who was living in Queen Anne Street, Cavendish Square. Manson shewed him the malarial parasite, which had been discovered by Laveran in 1880, and drew his attention to the 'crescents' (gametocytes) of *Plasmodium falciparum*. Fedschenko (1869), at the suggestion of the great German parasitologist Leuckart had established the fact that the guinea-worm *Filaria medinensis* passes a phase of its life-cycle in the water crustacean *Cyclops*. Manson in 1877 had discovered that another filaria of man, *F. bancrofti*, has a similar cycle of development in the mosquito. King in 1883 had written a most remarkable paper in which he gave nineteen reasons why mosquitoes are likely to carry malaria; whilst the ancient Romans had used mosquito-nets as a preventive measure against malaria—a practice which they appear to have borrowed from the Greeks, and which they in turn, as Herodotus remarks, appear to have borrowed from the ancient Egyptians. The ancient writings, including those of Susruta in India, contain many vague suggestions of the association of malaria with mosquitoes. To make a suggestion, however, is not equivalent to making a discovery. Manson suggested to Ross that malaria is conveyed by mosquitoes; he thought that the mosquito ingested the malarial parasites with the patient's blood; that it then fell into water when it died; that the infected dead mosquito or its remains were swallowed by man in his drinking water, and that man thus acquired infection with malaria. The true facts were discovered by Ross, but from first to last Manson acted as sponsor and gave him every encouragement. Ross returned from furlough to Secunderabad in 1895, determined to tackle the problem.

At that date there was practically no literature on mosquitoes, and Ross—not unnaturally—turned first to the 'grey' and 'brindled' mosquitoes, i.e., those of the genera *Culex* and *Aëdes* (*Stegomyia*). The stage of flagellation of the microgametocyte he immediately discovered, indeed it had been seen previously by Laveran in freshly drawn blood, and can be studied in fresh blood *in vitro* apart from the mosquito. In August 1895 he discovered the zygote or travelling vermicule of the malarial parasite, and in September of the same year he was suddenly transferred to Bangalore on special sanitary duty. To some extent, perhaps, Ross had himself to thank for the troubles that followed; he was a man who could tolerate neither fools nor authority patiently, whilst he sought—not to unravel—but to cut through red tape—an impossible procedure. Thus his views on his sudden transfer to Bangalore are given in the following stanza from his notebook at that date:—

> "We cry, 'God make us Kings,
> Poets or Prophets here'.
> The scornful Answer rings,
> 'First be My Scavenger'."

In 1897, however, Ross reverted to Secunderabad, and at Sigur Ghat suddenly came across a mosquito which was neither 'grey' nor 'brindled' but which had spotted wings, i.e., an *Anopheles*. The discovery gave him furiously to think. He turned to this

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

genus and on the 20th August 1897 suddenly came across a malarial oöcyst in an infected anopheline mosquito, the first and most important event in his great discovery. His first publication of this discovery was despatched to the *British Medical Journal* in September 1897, after he had further confirmed the existence of the oöcyst stage in infected anophelines, and was published in that journal on the 18th December 1897. He had no sooner reached this very important stage in his discovery than he was transferred to Bombay on military duty, and thence to Kherwara in Rajputana.

In the same year (1897) MacCallum discovered the process of fertilization in *Hæmoproteus columbæ*, the parasite of pigeon malaria, and the true nature of the malarial oöcyst now became clear. At Kherwara, however, cases of malaria and *Anopheles* mosquitoes were rare and Ross' work was interrupted. After insistent and persistent requests to be placed on special duty to investigate the problem, Ross was finally put on special duty for six months with instructions to investigate the transmission of both malaria and kala-azar within that period—a not inconsiderable task, seeing that the latter problem alone has taken twenty-three years of work, and the solution is not even now complete. With a comment of 'Victory or Westminster Abbey' Ross departed for Calcutta in March 1898.

In Calcutta, cases of malaria were rare, and Ross turned to the closely allied *Plasmodium præcox* parasite—or Proteosoma, as it is frequently termed—of birds. The stages of fertilization and of oöcyst formation of this parasite were immediately discovered, and in May 1898 Ross' first official report, *Cultivation of Proteosoma, Labbé, in grey mosquitoes* was sent in to Simla. This report was not officially issued until October 1898, but in the meantime some thirty or forty copies of it were sent to Europe, America and elsewhere. In June of the same year Ross discovered the liberation of sporozoites into the cœlomic cavity of the mosquito and succeeded in infecting healthy birds from infected *Culex* mosquitoes. He cabled to Sir Patrick Manson and Manson published an abstract of of the work in the *British Medical Journal* of June 18th, 1898. In July of the same year Manson gave an account of the discovery at the British Medical Association annual meeting at Edinburgh, and this address was published in the *Journal of Tropical Medicine* for August 1898, also in the *Lancet* in the same month, and in the *British Medical Journal* in September 1898.

In July 1898 Ross discovered the invasion of the salivary glands by the sporozoites, and—as he had previously succeeded in infecting clean birds by the bite of infected mosquitoes—the whole of the transmission cycle for *P. præcox* was thus discovered. In October 1898 Ross' *Preliminary Report on the infection of birds with Proteosoma by the bites of mosquitoes* was published from the Government Press, Calcutta. It now only remained to apply these results to man, and to work out the similar life-cycle of the human malarial parasites in *Anopheles* mosquitoes. Ross, however, had to leave Calcutta for Assam in August 1898, to take up the kala-azar investigation, with his malaria work unfinished.

He returned to Calcutta in November 1898, determined to finish the work. Unfortunately he started work with *Anopheles rossi*—the commonest anopheline mosquito of Bengal, but not a true carrier of malaria in Nature.

It is to be noted that, up to this point, Ross had worked out the whole of the transmission cycle of *Plasmodium præcox* in *Culex* mosquitoes, had seen oöcysts of human malarial parasites in *Anopheles* mosquitoes, and had predicted that the transmission cycle of human malarial parasites would be found to occur in *Anopheles* mosquitoes, and that it would be identical with that of *P. præcox* in *C. fatigans*. Also that advance copies of his first report had reached Europe and had been extensively circulated, and that the knowledge of his proteosoma discovery was widespread.

The Italian workers now entered the field. The question of priority with regard to the discovery of the sporongony cycle of the Plasmodiidæ has been the subject of endless controversy since that date, but there can be little doubt that the Italian workers were familiar with Ross' proteosoma work. Thus Grassi in his first publication in October 1898 (*Policlinico*) refers directly to Ross' work; in his second paper in November 1898 (*Lincei*) he refers to Sir Patrick Manson's address to the British Medical Asociation in the previous July, and states that he had received some of Ross' proteosoma specimens and mosquitoes from Manson. Bignami succeeded first in experimentally infecting man with malaria from *Anopheles* mosquitoes on November 3rd, 1898, and in his first paper in November 1898 (*Bull. R. Accad. Med. d. Roma*) discussed Ross' work at length. The Italian workers deserve every possible credit for applying Ross' results with proteosoma to human malaria, but their work can hardly be regarded as having been 'independent' of Ross' great discovery.

The Italian workers were greatly helped by two further events, the introduction of the Romanowsky stains, and Ficalbi's work on Italian mosquitoes which enabled them to identify the species of mosquitoes encountered and experimented with. Bastianelli, Bignami and Grassi (1898) observed the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

oöcysts of *P. falciparum* in anopheline mosquitoes—just as Ross had done in 1897. They also succeeded in infecting man experimentally from mosquitoes. Later in the year Grassi, Bignami and Bastianelli (1898) observed the complete cycle of development of *P. falciparum* in *Anopheles maculipennis*, and the partial development of *P. vivax*. Early in 1899 Grassi, Bignami and Bastianelli reported the development of *P. malariæ* in the same mosquito, and Bastianelli and Bignami (1899) that of *P. vivax*. Other papers followed by Grassi, Bignami and Bastianelli (1899*a*), Bastianelli and Bignami (1899), Grassi (1900), Ziemann (1900), and others. Ross himself left India on furlough in February 1899, and in the same year worked out the sporogony cycle of *P. malariæ* in *Anopheles* mosquitoes in Sierra Leone. In the meantime Ross' work on proteosoma had been confirmed—if it wanted any confirmation—by Koch (1899) and by Daniels (1899). Finally the whole sporogony cycle of the malarial parasites of man was described in full detail in a classical monograph by Grassi (1900). The full history of Ross' work and of his great discovery may be read in his *Memoirs*; whilst Nuttall (1901) has published a full account of the history of the discovery of the malaria transmission cycle, dealing with the papers published in their chronological order.

Thus, in the small laboratory at the Presidency General Hospital, Calcutta, there was made the tremendous discovery which will ultimately profoundly affect the health, the happiness, and the material welfare of more than half the human race. For Ross' great discovery meant that man can combat and can overcome malaria, both in its endemic and in its epidemic phases. Not only that; it led to the discovery of the mode of transmission of sleeping sickness and of kala-azar, to a thousand and one developments in tropical medicine and veterinary science.

We British are a strange race. We cover the Maidan of Calcutta with statues of second-rate generals and third-rate legislators, yet we have at present no permanent memento of Ross' great discovery. In Great Britain a Ross Institute and Hospital for Tropical Diseases at Putney Heath has been erected by public subscription and was opened in 1926 by the Prince of Wales. This institute is still badly in need of funds, and it is hoped that India will play an important part in supplying the deficiency. In India—prior to 1927—the only recognition of Ross' work has been the award to him in 1903 of the Barclay Medal of the Asiatic Society of Bengal—the only honour which it is within the power of that Society to bestow in recognition of original research work in the sphere of tropical medicine and biological science. His knighthood, his Fellowship of the Royal Society, and the Nobel Prize have all been honours which have been awarded to him from outside India. It is time—and more than time—to do tardy justice.

Sir Ronald Ross is to deliver certain lectures in Calcutta in January 1927. From what we know of him, we may anticipate that he will give utterance to no platitudes. It is far more likely that he will have not a few home truths to deliver, and that his lectures will contain both criticism and suggestion. For several years in our most admirable contemporary *Science Progress* he has preached the gospel of 'discovery and reward'; his splendid address on the management of medical research was re-printed in our issue for May 1924, p. 251, and it is not unlikely that Sir Ronald's visit to Calcutta will arouse widespread discussion and interest.

. . . . . .

In the second place, Sir Ronald's visit is exceedingly timely. As our readers are aware, the Government of India and the Indian Research Fund Association have recently taken the malarial situation in India seriously in hand. The Central Malarial Bureau at Kasauli has been expanded as far as its limited site in that small hill station will allow. Plans are being considered for the creation of an all-India Central Malarial Institute at Delhi or some other suitable site, with field laboratories, instructional classes, and the planning of malarial surveys. Three new malarial research posts under the Indian Research Fund Association have just been created, and these men will all be at work within the next few months. It has often been said that India has taken less advantage of the great discovery which Ross made in Calcutta than any other country in the world. Such a reproach, however, is not justified; it is lack of means and not of opportunity that has held back anti-malarial work in India during the last quarter of a century. Wherever the results of Ross' great discovery have been applied, immeasurable benefit has resulted to the populations concerned. The Americans—by a lavish expenditure of money—have been enabled to construct the Panama Canal, where the French had previously failed owing to the prevalence of mosquito-borne malaria and yellow fever; Sir Ronald Ross himself has been responsible for converting Ismailia on the Suez Canal from a malarial hotbed into the sanitorium of Egypt, for cleaning up Cyprus, and for much work in Mauritius. The work of Sir Malcolm Watson in Malaya has often been referred to in our columns, whilst the fine work of Lt.-Col. Phillips in connection with the labour force on the Sarda Canal scheme has also been referred to. Wherever funds and men have been available, malaria has been controlled, and—in some localities—almost exterminated.

From the days of the great discovery by Ross till now research work on malaria has followed on lines which were to be expected as a result of that discovery. Inasmuch as *Anopheles* mosquitoes were shewn by Ross to be among the greatest enemies of mankind, extensive work has taken place with regard to the identification of species—both in the adult and larval state, with regard to their breeding and seasonal habits, their distribution, and to determine what species carry malaria and under what circumstances. On the human side methods of diagnosis of malaria have been vastly improved, and the use of thick film and cultural methods in diagnosis introduced; the ætiology of relapses in malaria has received much attention; the pathology of the disease and—above all—the best methods of treating the patient have been the subject of countless papers and investigations. In brief one may say that to-day we know the main outlines with regard to world malaria; we have defined the objective of attack, to use a military phrase we have an 'appreciation' of the situation.

Simultaneously with the visit of Sir Ronald Ross to India, and with the vigorous anti-malarial policy of the Government of India, we are faced to-day with the fact that some of the great Indian commercial interests have become awake to the gravity of malaria with regard to their undertakings. The Indian Railway Board has taken up malaria as a railway disease and a railway problem of the greatest importance; in several railways whole time malariologists have been appointed, and already splendid results are being achieved. Thus in the construction of the new Bengal-Nagpur line for the new big harbour at Vizagapatam special difficulties were encountered, since the new construction runs through an intensely malarious and black-water fever belt. Mr. Senior-White, whose previous work in Ceylon under the Royal Society, and also in Malaya is well known, was appointed as a whole time malariologist. The result has been that in some of the camps the incidence of malaria has been reduced by 90 per cent. within a year; the whole situation is in hand and is being grappled with.

The Indian Tea Association takes malaria on the tea gardens of the Dooars and Assam very seriously. Under a special financial grant from this Association Dr. C. Strickland, Professor of Medical Entomology at the Calcutta School of Tropical Medicine, has carried out an extensive survey of malaria in the tea gardens of Assam, and his voluminous report is now ready for publication. Several of the big commercial firms concerned have employed experts of international reputation for short periods to study the local malaria problems on their gardens and to make recommendations. The Indian Mining Association is gravely concerned with the severe endemic malaria in Singhbhum and other adjacent districts, and the excellent reports by Colonel Christophers (1923, 1925), and Major Watts (1924) have thrown a whole flood of light upon the situation in these districts. In Bombay the work of Capt. Chalam (1924) in controlling malaria in the work on the Back Bay Reclamation scheme has been one of the few bright spots about that ill-fated venture. The cotton industry of Bombay is not neglecting malaria as one of its big problems—a problem rendered especially acute by the number of old disused tanks in the areas concerned, relics of the days before the introduction of electric power for the mills.

In the Military Department in India matters have profoundly changed within the past fifteen years. There is no longer the old-fashioned policy of employing a havildar and a squad of sepoys to indiscriminately oil any and every collection of standing or running water within cantonments in the vague hope of eliminating all mosquitoes—whether of genus *Anopheles*, *Culex* or *Aëdes*; military medical officers are expected to 'know their mosquitoes,' or at least to be able to put forward proposals for the control of malaria within a cantonment based upon a full and intelligent survey of the situation with reference to local conditions and seasonal prevalence. Throughout India district and municipal committees are paying increasing attention to malaria and to the need for its intelligent control. Finally, the evidence already given before the Royal Commission on Agriculture in India by the Public Health Commissioner with the Government of India shews that that Commission will be forced to recognise that if the welfare of his beasts and crops is of importance to the Indian *ryot*, his health and his ability to work his fields are of not less importance, and that malaria is the biggest problem in the public health of India.

. . . . . .

To summarise, we may say that never in the history of India has there been a moment when public interest has been more sharply focussed on malaria as the gravest problem in Indian public health. There is to-day no stinting of funds for the necessary measures of control; medical men and laymen alike recognise the supreme importance of the position. What is lacking are properly qualified and trained men for malaria survey work.

It is not the function of this journal to make suggestions in connection with so interesting and intriguing a situation; yet there are certain aspects of the present position that seem to us to require to be emphasized. Above and beyond all, it would seem that there is grave necessity for some co-ordinated

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

policy, in order that energies may not be frittered away and money wasted.

(1) In the first place there is apparent the need for continuous research work on malaria. It might seem, on a superficial study of the situation, that we already know so much about malaria that what is wanted is an application of our already garnered knowledge in the sphere of practical public health rather than an extension of that knowledge. Yet to come to such a conclusion is to entirely misread the situation. We may seem to know a great deal about malaria, but in reality we have as yet but grasped the bare outlines of the situation. With regard to man as a host of the malarial parasite, there are to-day dozens of unsolved problems. How do the malarial parasites produce the symptoms of malaria? It sounds an elementary enquiry, but it has never been answered. Abrami and Senevet (1919) consider that the rigor in malaria is a reaction of an anaphylactic nature, that either the merozoites liberated on rupture of the infected red corpuscles of the blood, or possibly the products of the destroyed red corpuscles themselves act as would an intravenous injection of foreign protein into the blood stream. The rigor in malaria is compared by these writers to that which follows on an intravenous injection of "T.A.B." vaccine in the non-specific treatment of arthritis. Further, what is the situation of the malarial parasite; is it inside or only upon the surface of the red corpuscles? How does man overcome malarial infection; is it due to the formation of immune bodies in his blood plasma, or to a sort of acquired tolerance? With regard to treatment, what is the best drug to use, what is the best way of administering it, and how does it act? Is prophylactic quinine of any use, or none? These are but a few of the big unsolved problems in malaria as it affects the human host.

Elsewhere in this issue will be found a most interesting and thoughtful essay by Mr. R. Senior-White, Malariologist, Bengal-Nagpur Railway, and Mr. Kenneth Williamson, formerly Malaria Research Worker, Federated Malay States, on the future of anti-malarial research. From the entomological aspect of malaria these authors shew that we are still profoundly ignorant. We know the various species of *Anopheles* mosquitoes and their selective breeding sites, which of them prefer sluggish water, and which of them running streams for instance. But there are a hundred and one facts which may profoundly affect the breeding of mosquito larvæ of different species. A slight change in the hydrogen ion concentration of the water or in its mineral content may transform a breeding ground into one quite unsuitable for the larvæ.

The food of the larvæ requires study, for a change in the algal flora of a breeding place may make all the difference between repletion and starvation of the larvæ. We know very little about the natural enemies of mosquitoes, and even less about their natural diseases. *Anopheles* larvæ are frequently parasitised by nematode larvæ and by protozoal parasites of the order Microsporidiida. Such microsporidial infections are apt to prove very fatal to the larvæ; just as in pébrine infection in the silkworm, so in microsporidial infection of *Anopheles* larvæ, the entire tissues of the larva become destroyed and very little is left except the lumen of the intestinal tract and the cuticle. Such infections spread very rapidly in a pond; in a pond where the infection is present the larvæ may all die off rapidly, whilst in another pond a few yards away not a single larva may be infected. Might it not be possible to utilise these natural enemies and infections of mosquitoes for their extermination at a cheap cost? There are a hundred and one aspects of the problems of malaria calling aloud for investigation.

The men to carry out such work are few and far between. Protozoologists, entomologists, and biochemists are not born, but made—usually made by many years of personal study, reading, and investigation. It is not every worker who has the faculties and the adaptability needed for research work. Yet if we are to get a move on with the problem, such men must be appointed; and often teamwork by men in different branches of malariology will be called for.

To take such men and place them on ordinary malarial survey work is a waste of men and a waste of money. It is like using a sledge hammer to crack a walnut. Industrial concerns cannot afford their salaries for prolonged periods of investigation, whilst less highly skilled but fully trained officers of lower grade can do the work, if properly supervised.

(2) It is facts such as these that face the commercial industries of India and still more so the Provincial and Imperial Governments, and District Boards and municipalities when they try to grapple with malaria, and which hold up progress. Paris green is one of the cheaper larvicides recently introduced. The Public Health Service in the vicinity of Lake City, Florida, carried out an experimental investigation on the cost of hand dusting with Paris green, and found that the approximate cost was $5.90 per application per acre. Where large collections of standing water have to be dealt with, King and Bradley (1926) have shewn that dusting by aeroplane is probably considerably cheaper, and the photograph below of this process is reproduced from their article in the *Journal of Tropical Medicine and Hygiene* (Vol. XXIX, No. 18, p. 312), and illustrates one of the newest methods of mosquito control.

(3) And this point brings us to the third important fact in the problem of the control

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of malaria in India. Present-day measures are too costly. A few figures from Sir Ronald Ross' book on the *Prevention of Malaria* will illustrate this. The Americans reduced the annual death rate from malaria among the workers on the construction of the Panama Canal from 11.59 per thousand in

Dusting the marginal zone of Field Lake with the wind blowing towards the lake; the plane was flown outside of the tree line and the dust drifted into the breeding area.

From:—The *Journal of Tropical Medicine and Hygiene.*

1906 to 1.23 per thousand in 1909. Yet the annual expenditure incurred on sanitary measures was approximately $3.50 *per capita*, of which approximately $2 *per capita* was expended on anti-mosquito work. If a similar proportion was to hold good for India—a land with more than 350 million inhabitants—a sum of two to three thousand crores would be required to produce a similar result. In Italy in pre-war days the cost of subsoil drainage to check malaria worked out at about 8 guineas per acre of land, and quinine prophylaxis and screening were largely resorted to as cheaper measures. At Ismailia approximately 2,000 cases of malaria occurred annually before anti-mosquito measures were adopted; there were 2,284 admissions to hospital for malaria in 1900 and the Canal Company contemplated the abandoning of the station, which de Lesseps had intended to be the commercial capital of Egypt. Sir Ronald Ross started work in 1902, and by 1906 malaria had been abolished from the station, no fresh cases occurring in 1906 and 1907. The capital cost of the operations was approximately £2,000 and the annual recurring cost about £1,000. In Cairo Sir Ronald Ross estimates that it would involve an expenditure of about £20,000 annually to clear the city of mosquitoes.

(4) As matters at present stand, when an industrial concern wishes to grapple with malaria amongst its labour force, what may appear to be an expensive policy at first sight often turns out to be the cheapest in the end. The first essential is to secure the services of a properly trained investigator to carry out a detailed investigation lasting over a period of twelve months. Only when a full and detailed knowledge of the local and seasonal conditions present has been acquired can the campaign against malaria on the estate be properly drawn up and carried out. Indiscriminate anti-mosquito measures applied by some local medical officer with no special training in anti-malarial work are almost useless, and any expenditure incurred in having the situation fully studied before measures are taken is fully justified.

It ought to be possible to get such a type of man in India on a salary of from Rs. 350 p.m. upwards, but the supply of such men is at present entirely inadequate to the demand for them. In a recent *viva voce* examination for an Indian university D. P. H. the writer asked the candidates which were the important species of *Anopheles* mosquito which carry malaria in India, and what were their special breeding places. Not one of them had any idea; they could distinguish an *Anopheles* from a *Culex*, and that was all. Yet such post-graduate students are the men who will be called upon to serve as District Health Officers and to tackle malaria within their districts. We have got to make a real effort in India to train Indians of the right class for anti-malarial work; and they must be men of the right stamp, who will not be afraid to explore jungle and swamp, to use their energy and brains.

Even the text-books for teaching such students are almost lacking at present. Stephens and Christopher's invaluable manual on *The Practical Study of Malaria* is out of print. The small book on *Mosquito Reduction and Malarial Prevention* by Captain Crawford and Dr. Chalam, just published by the Oxford University Press at Rs. 3, and reviewed on p. 51 of this issue of this journal is a good start in the direction of providing a text-book, but is of rather an elementary character. It is eminently suitable for assistant and sub-assistant surgeons, and should prove most useful to junior workers in India. A larger and more detailed text-book on the subject is at present in course of preparation at the Calcutta School of Tropical Medicine, and it is hoped that it will be published within the next few months.

Whatever the organisation adopted for the training of medical men in India in malaria investigation and control, there can be no doubt as to the need for such trained workers in the field in India.

In carrying out well planned measures it is not essential to employ *medical* men, so much as properly trained men. At Khartoum

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

much of the supervision of sanitary and anti-mosquito work has been carried out most successfully by trained non-commissioned military officers. Indian labour—especially Indian coolie labour—is apt to be inefficient unless it is properly supervised, and personality counts for much in the selection of the right type of supervisor.

. . . . . .

In whatever way the situation in India develops during 1927 and subsequent years, it is clear that we are on the verge of important advances. A demand for research workers of the highest ability is bound to arise, also a still more urgent demand for trained investigators in anti-malarial work. Central organisations, provincial organisations, and industrial organisations—each for the industry concerned—are likely to arise. The future is full of promise, but it is important that schemes and plans shall be co-ordinated and be well planned. In a word the situation calls for a well defined policy.

BRIEF NOTES ON THE LIFE AND WORK OF SIR RONALD ROSS.

(Made for the most part from the *Memoirs* by *Ronald Ross*. London: John Murray.)

SIR RONALD was born at Almora in the Kumaon Hills in 1857 (3 days after the outbreak of the Indian Mutiny).

The date of his birth (13th May) is said to be the most unlucky of all birth-days. Sir Ronald's comment is "Those who enter the world on that day may console themselves by attributing all their failures to misfortune and therefore all their successes to merit."

His first memories are of mountains, snows, rhododendrons and fir-trees, his next of a father sick with fever lying in a palanquin in a burning plain.

Ross lived in India till the age of eight, when he was sent to England. At school his chief interests were mathematics, drawing and music. As a student at St. Bartholemew's Hospital he describes himself as taking little interest in his medical studies, music and poetry being more to his liking.

He entered the Indian Medical Service and came to Madras in 1881. Even now his medical work did not attract him and most of his time was spent in studying in the original languages the works of Tasso, Alfieri, Racine, Hugo, Schiller, Gœthe, Homer, Aeschylus and Virgil. The composition of poetry still engaged much of his attention and while in Madras he wrote a poem ending with lines which sound almost prophetic of the part that he was destined to play in the improvement of human environment.

"O Heaven, shall man rebelling never take
From Fate what she denies, his bliss?
Cannot the mind that made the engine make
A nobler life than this?"

In 1882 what he called his "great calamity" occurred; this was the reading of a book called "The Orbs of Heaven" which so fired him with zeal for the study of mathematics that the next five years were spent on various branches of that science, his relaxation taking the form of writing poetry.

During these five years he saw service in many parts of India and also in the Andaman Islands.

In 1888, thoroughly worn out by intensive study and the climate, he returned to England, where he suddenly discovered a zeal for medical work and took the D.P.H. of the Royal Colleges of Physicians and Surgeons. He also took out a course of study in the new science bacteriology, under Professor Klein. At the end of his leave in 1889, a novel which he had written in India was published; this met with a very mixed reception, but evidently it had great merit as it called forth a spontaneous letter of praise from Rider Haggard.

During the next four years Ross became much interested in the fevers of India on which he wrote a poem containing these lines—

In this, O Nature, yield I pray to me.
I pace and pace and think and think and take
The fevered hands and note down all I see,
That some dim distant light may haply break.
The painful faces ask, can we not cure?
We answer No not yet; we seek the laws.
O God, reveal thro' all this thing obscure
The unseen small, but million murdering cause.

These lines may well be regarded as a prayer which was to be answered in after years.

The next spell of leave was in 1894 and till then his interest in literature was a serious rival of his medical work. A book called "Spirit of Storm" was published by Methuen and Co. and received very favourable reviews, especially one by Mr. Stephen Gwynne, who described it as a "very notable book." Now his attention was turned very seriously to the study of disease and he was awarded the Parkes' Memorial Medal for the best essay on malaria.

He returned to India early in 1895 and the next four years of his life were devoted almost entirely to investigations in malaria.

The first great discovery in malaria had been made in 1880 by a French Military Surgeon, Laveran, who discovered the parasite which causes the disease. At that time the knowledge of the infinitely little had made such feeble progress even among medical men that small importance was at first attached to it, and it was not till some years later that the discovery was generally accepted.

Some savants had already suggested that mosquitoes had something to do with the spread of malaria, but when Ross started his work no one had the slightest suspicion of the means by which the disease was carried. It was not till 1894 that Ross first saw a convincing specimen of a malaria parasite, Sir Patrick Manson being his instructor. Manson had a strong conviction that mosquitoes carry malaria, his hypothesis being that the parasites develop in the body of the mosquito; when the mosquito is drowned in water the parasites infect the water, and the disease is conveyed to the patient by the water in which the infected mosquitoes have been drowned.

Ross started to work in Secunderabad in 1895. His enthusiasm for microscopical work was great and his first effort was to allow mosquitoes to suck the blood of persons suffering from malaria and to test the truth of Manson's view by causing human beings to drink the water in which the fed mosquitoes had been immersed. The result was, of course, negative.

A period of intense work was interrupted by a transfer to other duties and it was not till June 1897 that Ross returned to Secunderabad and took up his malaria investigations again.

On the 20th August 1897, Ross found that malarial parasites in blood which had been sucked by dapple winged mosquitoes underwent the degree of development which had previously been noticed in blood on a glass slide, and also grew in the stomach wall of the mosquito into a large rounded form. Ross was greatly excited as he thought he was on the point of completing the essential stage in the further development of the parasite, but at this point he was ordered to Kherwara in Rajputana where there was no malaria.

By the efforts of Manson, Ross was placed on special duty for six months from February 1898. On arriving in Calcutta he found that he was expected to solve not only the malarial but also the kala-azar problem in the half-year which was allotted to him.

One of his first disappointments was to find that there was no reference medical library in Calcutta, the next was that there was little malaria. Failing to find human material he tried experiments with birds, sparrows, larks and crows which often harbour parasites which closely resemble malarial parasites. Soon he found that *Culex* mosquitoes which had fed on infected sparrows showed the same kind of bodies which he had found in infected mosquitoes

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in Secunderabad. His first report to the Director-General was made on the 21st May 1898. By July, his work had reached the stage in which he discovered that the parasites found their way into the salivary glands of the mosquitoes. He also found that when infected mosquitoes were allowed to feed on healthy sparrows, these sparrows in a fortnight showed swarms of the parasites in their blood, while control healthy sparrows remained free from parasites. Every competent scientist at once realised the immense importance of the discovery. It only remained for other workers to go over the same ground using human beings instead of sparrows and the dapple winged or *Anopheles* mosquito which had already been the subject of Ross' own experiments in Secunderabad. Ross himself was absolutely certain that he had completely solved the problem. He indicated clearly what remained to be done to complete the experimental demonstration of the means of conveyance of human malaria.

In due course within a very short space of time other workers, who followed exactly the indications laid down by Ross, found that just as he had predicted the same series of events followed when suitable mosquitoes were allowed to feed on human beings suffering from malaria. These mosquitoes when allowed to survive for a few days were shown to be capable of conveying the disease to other human beings. The pity is that some foreign workers claimed to have done this work independently of the discoveries of Ross, but they are convicted by their own writings of having had the fullest knowledge of the work done by Ross, and now the scientific world is absolutely unanimous in giving the sole credit for the discovery to Ross, though even now there are many who are not aware of the completeness of his work. One misconception persists very strongly and for this Ross himself is partly to blame. This consists in attributing to Sir Patrick Manson the origination of the hypothesis of the mosquito transmission. It is true that Manson was strongly of opinion that the mosquito is concerned in the transmission of malaria, but as stated above he thought that the parasite developed in the mosquito which afterwards infected water, so that according to this hypothesis the disease would have been conveyed by drinking infected water. As we have seen, Ross at first followed up this scent but it only led him astray. When the discovery was completed, Ross generously reported that Manson's great hypothesis had been vindicated, and the world cannot be blamed if undue credit was given to Manson. In a sense the discovery of Ross was due to Manson, for it was the encouragement and advice of Manson which were largely responsible for the labours of Ross.

Ross complains with good reason that so little recognition of his work came from India. Indeed, almost the only public recognition of his discoveries came from Calcutta; the Asiatic Society of Bengal awarded him the Barclay Memorial Medal in 1903. It would, perhaps, be best to pass lightly over this failure of India to do justice to the greatest of her workers, but a reference to it may suggest the best means of doing penance for past neglect, this will undoubtedly be to promote with zeal further research in malaria and the anti-malarial work which has been made possible by the "great discovery."

In spite of the full recognition which was accorded to the work of Ross by scientists, some of his most ardent admirers did not realise its supreme importance. They admitted that Ross had shown that malaria could be transmitted from man to man by the mosquito, but they thought that his method was only one of several and perhaps the least important. Ross alone had the clearer vision which enabled him to see that any other mode of transmission was exceedingly unlikely and from the first he preached in season and out of season the gospel of malaria prevention by mosquito control. "As every schoolboy knows," Ross was right, mosquito control is the same thing as malaria control. No mosquitoes, no malaria!

In another respect his visions of the future were wrong, he thought that in two years malaria would be stamped out of every city and large town in the tropics, at least in those that have sanitary departments such as exist in British possessions. On his voyage home to England in March 1899 his mind was much occupied by dreams of the great cleansing which the tropics would undergo, he imagined the heads of the India Office, the Colonial Office, the War Office and the Foreign Office setting the whole machinery in motion within a few weeks. Such thoughts cheered the wearied victor after his exhausting battle. Bitter disillusionment was to follow. Instead of the honours and rewards which he anticipated for Manson and himself he found that a post with a salary of about Rs. 300 a month guaranteed for three years was all that was offered to him. This post he accepted as it seemed to offer a prospect of carrying out his policy of expeditions to the tropics and experiments in sanitation. Towards the end of 1899 he went to Sierra Leone where he was successful in completing his work by proving that the *Anopheles* mosquito was able to convey malaria from one human being to another, he also laid down very complete plans for the control of the disease and so comprehensive were these that it was by following them that all the great successful experiments in freeing the Panama Canal zone and other areas were afterwards carried out. It is nothing short of miraculous that one man has been able, almost unaided, to discover not only the means by which malaria is carried but also the means by which the disease can be controlled.

Another point of importance is that the discovery was by no means the result of chance, it was a case of forming a hypothesis which appeared to account for the known facts, then testing

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

that hypothesis, and when it was found to lead in the wrong direction seeking out another trail until at last the truth was made known.

Those who knew most about the subject were the people who were most quickly convinced of the value of the great discovery, but it is safe to say that Ross himself was the only one who appreciated rightly the enormous significance of his own work.

In 1902 Sir Ronald had the opportunity of making the first great demonstration of the vast possibilities of his discovery by freeing Ismailia of malaria at a time when the evacuation of the town was being seriously contemplated. Soon after his return from Ismailia in December 1902 he was awarded the Nobel Prize of nearly £8,000, being the second recipient of the prize for medicine. This was the only substantial reward which he received for a discovery which has been worth many millions of pounds to the human race apart altogether from the saving of life and the prevention of sickness.

The after work of Ross has consisted in teaching the world how to prevent malaria. To some extent this was a thankless task, his discovery was made too soon, the intelligent sections of the world were not sufficiently well educated to realise the importance of his work, so that his teaching met with apathy and indifference except from a few enlightened men who converted his precepts into practice, to the great benefit of themselves and of the human beings whose lives they saved.

The Panama Canal could never have been constructed but for the work of Ross, even this great object lesson has not dispelled the inertia of the world and there are still vast areas which are lying desolate which might be converted into fruitful fields if only the advice of Ross were carried out. Some of the more important honours and awards which were made to Ross are:—

Fellowship of the Royal Society ..	1901
C. B.	1902
Nobel Prize	1902
Royal Gold Medal, Royal Society ..	1909
K. C. B.	1911
K. C. M. G.	1918

It will be noticed that the adequate State recognition of his work came years after his greatest work was done, and it was only the other day that the Ross Institute was opened by H. R. H. The Prince of Wales. The object of this institute is to honour Sir Ronald and to continue the work on malaria which lies so near to his heart.

It is to be hoped that Sir Ronald will be spared to see the adequate recognition of his discovery in the form of energetic practical application of the principles which he laid down so many years ago.

J. W. D. M.

SPECIAL ARTICLES.

THE DISPENSARY TREATMENT OF MALARIA IN INDIA.

By A. H. PROCTOR,
LIEUT.-COLONEL, I.M.S.,
Superintendent, Presidency General Hospital, Calcutta.

OF late years there has been a constant agitation in India for the establishment of Ayurvedic dispensaries. Also Government has been asked to establish training schools for Ayurvedic practitioners. Educated in an English school of medicine, I believe modern medicine of to-day to be superior to any indigenous school. Yet after seventy years of experience of practitioners trained on the same lines in this country, many educated Indians and the great bulk of the population of India are not converted to this belief. Religion, the strength of tradition and political considerations all account to some extent for the failure to convert the people of India to the superiority of modern methods in medicine. (I purposely do not speak of any special school or system of medicine because at the present day the modern school of medicine is prepared to accept and incorporate in its own teaching any proved facts of value.) I believe however that the main factor in this failure to convert the masses, is their actual experience of modern medical practitioners. To the bulk of the population the representative of modern medicine is the district or municipal dispensary, in charge possibly of an assistant surgeon, but more often of a sub-assistant surgeon.

If I were asked to select a disease in the tropics to prove the efficiency of modern methods, I would select malaria. Its diagnosis with a microscope is easy and certain, its treatment well defined and simple, and the result of treatment rapidly obtained. What then is the experience of the *ryot* when he applies to the representative of modern medicine for the relief of malaria?

My former district is a malarious one, and the principal disease treated in it is malaria. I investigated the records of four typical dispensaries and the experience of 698 patients with malaria. The results are as follows:—

One attendance	48 per cent.
Two attendances	20 per cent.
Three attendances	12 per cent.
Four attendances	8 per cent.
Five attendances	4 per cent.
Over five attendances	8 per cent.

These figures are for all four dispensaries, but when worked out for individual dispensaries they were found to be practically the same. Where a patient attended over five times there was as a rule some obvious

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

explanation. Thus out of three cases at one dispensary, one was the medical officer's son, one the dispensary servant, and the third the station-master's son. In another dispensary out of eleven cases registering over five attendances, five cases belonged to the family of the postmaster living a few yards away, two cases had, from the start, been represented by friends, and may not have been malaria, while two more had registered over twenty-five attendances up to the point I followed them, and I think we may assume they were not malaria. What do these figures prove? To the cheerful optimist that 48 per cent. were cured by one attendance and 20 per cent. by two. To the pessimist 48 per cent. never came back because they concluded that it was not worth the time and trouble. Where lies the truth? We may be guided to a correct conclusion by ascertaining the treatment these patients received.

On enquiry I was informed that each case was given three doses of the stock quinine mixture, *if he brought a phial.* If he did not he got one dose. There was no provision to give the patient a phial. If the patient came from a distance he got six doses, but that was only if he specially appealed for it. I gained the impression that this was more an answer to my question than a fact. The stock mixture of the dispensary pharmacopœia is ten grains of quinine to the ounce, but in three out of the four dispensaries it was only made up to half that strength, the reason being that the quinine supply was not sufficient to last the year if made up in the official strength. An analysis of one of these stock mixtures further revealed the fact that it only contained three grains to the ounce.

From the above facts I think we may safely conclude that at least 92 per cent. of patients suffering from malaria received insufficient quinine to cure their malaria and that some of the remaining 8 per cent. were not cases of malaria and so were not cured.

Is it to be wondered at that the people have little faith in modern medicine? It gives them little more than the Ayurvedic system and a good deal less than some patent medicines for malaria.

Recent observations go to prove that 30 grains of quinine in solution daily, given for three consecutive days, will cure 43 per cent. of cases of benign tertian malaria. Relapses occurred in the remaining 57 per cent., but in the great majority of these cases the parasites and fever either disappeared spontaneously or as the result of one more three-day course of quinine.

Surely we can so organise our medical relief that each case of malaria shall receive 90 grains of quinine in solution when he visits a dispensary? It is not reasonable to expect a malaria patient to walk several miles daily to obtain 15 grains of quinine. Even when he does do so, he may only get 9 grains as the recent analysis shows.

Why are these inadequate quantities given? Primarily the difficulty is one of finance. To take one of the dispensaries investigated, its requirements in quinine at 90 grains per case would cost Rs. 720 per annum. Its total budget allotment for drugs, medical and surgical requisites, etc., is Rs. 500 per annum. It actually spends on quinine Rs. 288 per annum, and receives in addition quinine to the value of Rs. 144 from the Public Health Department; a total of Rs. 432 per annum. There are some dispensaries better than this and some worse, but all are in the same position as regards finance. We must also remember that adequate treatment would result in an enormous increase in attendances.

We come now to the second factor in our failure to convert the people to a belief in the superiority of modern medicine. Are the medical officers in charge of these dispensaries good representatives of modern medicine?

Three of the dispensaries have been supplied with good microscopes. One of them was in use when I inspected the dispensary, the medical officer being a graduate of the Calcutta University. In the case of the others the microscopes were locked away, and the medical officers frankly owned that they did not know how to use a microscope. Is there not something very seriously wrong with our system of medical education and examination when we find a registered practitioner in a tropical country unable to make use of a microscope for ordinary clinical work?

The latest development in medical policy in Bengal is the starting of medical schools in various districts, and the utilisation of the Sadr hospitals for training sub-assistant surgeons. Is this a sound policy? I venture to think not.

With ten candidates applying for every vacancy in the Calcutta Medical College would it not be better to extend the opportunities for training to university standards? Granted enough graduates are turned out, economic pressure will drive them out into the districts. The sub-assistant surgeon was originally trained to work under supervision. His very title implies that. At the present day he is being put in independent charge, and although a limited number are doing well, the vast majority are not, if judged by the standards of modern medicine.

Nor are our Sadr hospitals suitable training-grounds. We must remember that a student's training-school represents to him the highest ideal to which he must work up to. Are any of our Sadr hospitals even representative modern hospitals? We have only to think of their limited staffs, their unsatisfactory buildings, their poor sanitation, their poor equipment, their lack of special departments, their almost absolute lack of nursing

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to realise that they are not. Can anyone compare, say the hospital at Chinsura, with one of the provincial teaching hospitals in England, such as Manchester or Newcastle, and not realise how inadequate it is to turn out satisfactory representatives of modern medicine?

Starting with a good general education, studying in his own language, and with a knowledge of chemistry and physics, the General Medical Council of the United Kingdom has laid down that five years is the minimum period in which a student can acquire a working knowledge of modern medicine. Even then it is complained that the curriculum is overcrowded and that extra time must be spent on tropical diseases, if the graduate is going to practise in the tropics. Starting as we do in India with a poorly educated student, whose text-books and teaching are in a foreign language, can we aspire to achieve that minimum in the same period, or less? The scattering of these under-trained medical practitioners over the country is I believe undermining what little faith the masses have in modern medicine, and paving the way for the revival of the indigenous systems of medicine.

It was Flexner who pointed out that in the big towns a bad doctor could make his living, but not in the country. In the town his mistakes were not common knowledge, but in the country every one heard of them. The theory that the poorly-trained doctor will be content to stay in the *mofussil* villages, will, I think, prove incorrect. He will make his small income more easily in the towns.

THE FUTURE OF ANTI-MALARIAL RESEARCH.

By RONALD SENIOR-WHITE,
Malariologist, Bengal Nagpur Railway,
and
KENNETH WILLIAMSON,
Professor of Biology, Singapore Medical College and recently Malaria Research Officer, Federated Malay States.

'Go where Death's pickets hide—
Unmask the shapes they take,
Whether a gnat from the waterside,
Or stinging fly in the brake,
Or filth of the crowded street,
Or a sick rat limping by,
Or a smear of spittle dried in the heat—
That is the work of a spy.'—*Kipling.*

Introductory—the general need for research.

ALTHOUGH Kipling wrote these lines more than twenty years ago they summarise almost the whole activity of tropical medical research, even at the present day. And his instinctive sympathy for the worker, who, whatever his work, has to contend with the intractability of things or of men, lent him insight.

We are not concerned to describe the ravages of malaria since these are already well known: but a correct idea of their magnitude is necessary in order to appreciate the possible value of research, considered as an investment which will diminish them. Malaria extends round the world, being found in places so far north as the Baltic, and so far south as Natal. Far from being confined to the tropics, as is well known, many parts of Southern Europe, notably Italy and Greece, contain foci of virulent infection. In a recent address Dr. Andrew Balfour has estimated that the annual death roll from malaria is 200 millions, and that the annual loss to the world which it occasions is between 50 and 60 millions sterling. These figures are certainly not exaggerated, since in India alone one million three hundred thousand persons died of malaria in 1920, and it has been estimated that in 1923 there were ten million cases in the Russian dominions. The disruption and delay caused by the death and sickness of labourers occasions incalculable loss to organised industries, and even to agriculture, since neither ploughing nor reaping wait upon convalescence. Apart from the misery and loss occasioned by actual sickness and death, the invalidism caused by chronic malaria robs inspiration, and by depleting vital energy, levies a heavy toll upon both European and native initiative in the tropics. Therefore without reference to humanitarian considerations, and using an expression derived from the clarified preceptions of finance, the "present value" of any discovery making it possible to eradicate malaria, or even considerably to increase the ease, and diminish the cost of dealing with it, would amount to hundreds of millions of pounds. Yet only a few thousand pounds a year are spent on malarial research in the Empire. There seems to be no escape from the dilemma, either that practical men are not really practical in their dealings with malarial research, or that there is very little to be hoped from it.

This supposition involves two alternatives, namely either that research is bankrupt, and that money spent on it must therefore necessarily be money wasted: or that existing preventive measures are so nearly perfect that no better are needed. We believe that the last supposition is almost the exact opposite of the truth. This we will briefly proceed to show, devoting the remaining pages to a discussion (necessarily limited) of the enormous possibilities of anti-malarial research, organised on a world, or at least on an Empire-wide scale, and carried forward unflinchingly, with bold and wide-ranging initiative, under enlightened and really scientific guidance.

The defences against malaria are twofold. Either the parasites which cause it may be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

attacked and killed while they are in the blood, or attention may be directed to getting rid of the anopheline mosquitoes which transmit them from man to man. The reader may be reminded that the word malaria stands for a trinity of ill, there being at least three different species of parasite, namely that of quartan, that of the much commoner tertian fever (the so-called "benign"), and that of the sub-tertian (or "malignant") form.

Despite the fact that over 900 synthetic drugs have been tested on syphilis, and over 200 on sleeping sickness, anti-malarial research on these lines has received much less, and much too little, attention. The result is that quinine, in one or other of its modifications, is still the remedy at present in almost universal use. The history of quinine treatment, summarised by Dr. William Fletcher in his reports from the Institute for Medical Research of the Federated Malay States, is a curious one.

As everyone is aware, the medicinal value of cinchona bark, which was introduced into Europe by the Jesuits in the sixteenth century, was discovered by the Indians of Peru. This discovery, like that of oiling, is therefore pre-scientific. Quinine, which is but one of the alkaloids present in the bark, is obtained by an elaborate and costly process of purification, which is largely unnecesary. For though it is true that some of the other alkaloids are harmful if they are prescribed in excess, others, rejected without cause, are proving of even greater value than quinine. And as long ago as 1866 a committee appointed by the Indian Government reported that the much cheaper cinchona febrifuge was as good an anti-malarial remedy as quinine. In spite of this fact, the only species of cinchona now grown is one which was selected because of its richness in quinine, and it is difficult to grow in many parts of the Empire suited to other species, with the result that its cultivation is almost confined to the Dutch East Indies.

Quinine, although the best available drug, is not a perfect one. To quote Dr. Fletcher, "Stephens found that 54 per cent. of his series of benign tertian cases relapsed within 21 days" after having been given 20 grains or more of quinine daily for four weeks; and he records that Acton found that 75 and 80 per cent. of benign tertian and quartan cases respectively relapsed after thorough-going quinine treatment. But a still greater objection to quinine is that its cost is prohibitive. The Dutch growers have restricted production for several years past because the people in malarious countries are too poor to buy quinine: and few Governments can afford to distribute it free, and none have so far been able to devise means for its effective distribution and long-continued consumption by the people in the large quantities necessary. In the meanwhile a sub-committee of the League of Nations has been considering means for cheapening quinine. But Dr. Fletcher has confirmed the old belief in the efficacy of the much cheaper cinchona febrifuge, prepared from the crude bark, and finds it even more efficient than quinine against quartan, while Major Acton in India found it superior for the treatment of benign tertian fever, a result he attributes to the presence of the alkaloid quinidine. What is wanted, however, is a cheap and much more powerful specific, able rapidly to eliminate the malarial parasites from the blood of a whole population. If this could be done, malaria should cease to exist. It could be abolished by simple administrative action comparable to compulsory vaccination. For if the parasites in the blood of a whole people were killed and prevented from re-establishing themselves, by the conferring of complete immunity on the population for a period only as long as the life of a single generation of mosquitoes, malaria would be stamped out.

A million pounds (and a very small fraction of this might suffice if it were expended directly, and not invested) spent upon the discovery of such an agent (be it a serum, vaccine, jungle herb, synthetic drug, unknown ray, or something as yet entirely unimagined) would repay itself scores of times over in twenty years.

The malarial problem is full of seeming contradictions any of which when resolved by investigation may shed a flood of light upon the causation of malaria. Why for example has the disease to all intents and purposes died out in England, although two of the most dangerous carriers, *A. maculipennis* and *A. bifurcatus* are still abundant? Even more strange, if true, is the rarity of locally contracted malaria in Kashmir, where not only are the appropriate mosquitoes present, but also convalescents from the plains of India, many of whom must harbour parasites in their blood. All that is comprised under climate and topography, including humidity, temperature, and altitude, possibly even electrical conditions and their direct effects upon man and the mosquito, as well as indirect ones exerted through local vegetation, micro-organisms and food supplies, makes up an interwoven tangle of cause and effect, which serves to illustrate the complexity of the malarial problem, and the need for penetrating study of it on the spot. This is being carried out by Colonel Gill, whose pronouncement will be awaited with interest, for every local problem carried a step nearer to solution clears the horizon, and affords clues which may be helpful elsewhere.

Turning to the available methods of mosquito-control, the protection they afford against adult mosquitoes is admittedly very inadequate. This is proved by the fact that

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

when mosquitoes are at all numerous we are forced to screen the doors and windows of houses, or to take refuge within mosquito-nets. Apart from the possibility of fumigating small closed rooms, the destruction of winged mosquitoes is compassed by swatting or capture by hand, or by the precarious use of darkened but unbaited traps. Since no bait with the power of attracting mosquitoes through their sense of smell is known at present, traps are ineffectual during the hours of darkness when most species are on the wing. On the other hand repellent substances, besides being fugitive in their action, are unpleasant for the user, and often cause him more inconvenience than they do the mosquito.

Despite the growing popularity of copper arsenite and other powders, the oiling of their breeding waters is still almost everywhere relied upon for the destruction of larvæ and pupæ. Strangely enough the employment of oil for this purpose ante-dated Sir Ronald Ross' discovery by more than eighty years, the first known reference to it, according to Dr. M. E. Barnes of the Rockefeller Foundation, being in a London publication of the year 1812. The discovery of the efficacy of oil, like that of the cinchona, is therefore a pre-scientific one. Whether or not its continued use at the present day is to be regarded as in any sense a reproach must be a matter of individual opinion. The mode of its action, partly by suffocation and partly by poisoning, has at last been elucidated, and the cause of its spreading over water explained; while improved oiling fluids have been discovered.

One of the chief disadvantages of oiling is that it must be repeated at intervals of every few days, and be carried out under expert supervision. These facts necessarily render the process costly.

Rubber estates, almost alone among agricultural lands, have proved profitable enough to provide for the necessary expenditure. In very many of them oiling is resorted to, either of free choice as the lesser of two evils, or under Government compulsion; and tens of thousands of pounds are spent annually with far from completely satisfactory results.

The only serious rival to oiling is sub-soil drainage. Both alike are so costly that there is not a shadow of chance that they will ever be applied to anything but an insignificant fraction of the vast tracts of land infested by malaria all over the world. Kuala Lumpur, the Federal Capital of the Malay States, with a population of between eighty and a hundred thousand, is an example of what can be done by the highest engineering skill, coupled with expert and slowly acquired knowledge of the breeding habits of the local mosquitoes. Malaria has been almost abolished in the town by open and sub-soil draining of about ten and a half square miles, carried out under the supervision of Mr. F. D. Evans at a capital cost of over £60,000, and a yearly maintenance charge, exclusive of the cost of oiling the open drains, of over £2,300 per annum. It is rightly urged that by a no means negligible portion of this expenditure is covered by increase of land-values and of rents. This, however, is an argument only applicable to towns, and by no means answers the question where anything like £6,000 capital expenditure, with a recurrent annual charge of over £200, per square mile, is to come from anywhere else.

Leaving the considerations of anti-malarial measures as they are at present carried out, let us glance (for no more is possible) at the problems with which research is confronted. Only certain species, of only a single genus, *Anopheles*, have been proved to carry malaria. The work of classification, which was undoubtedly the pre-requisite of further advance, has now been well nigh completed; and, whereas at the beginning of the century only fifteen species were known, the genus now contains a hundred and twenty-seven. The devoted labours of busy medical men the world over, assisted by only a few professional entomologists, accomplished pioneer work in this direction, as in determining which are the dangerous species, and in investigating their breeding places. Doubtless a very great deal yet remains to be discovered, especially in respect to the possibility that many as yet unstudied species of anophelines may carry malaria. But in spite of a lamentable scarcity of investigators, this work is well started, and may be trusted to proceed on well-known lines.

The influence of the female mosquito's food, which besides blood, consists mainly of fruit juices, upon its power of transmitting malaria, has yet to be studied. In the case of larvæ we know very little about what they feed on, and nothing at all of how they digest their food, what they will tolerate, and what will make them sick. But research is beginning to make it certain that the larvæ of different species differ radically in their requirements and tolerances. Yet all are attacked alike, and their suppression atempted by methods which, if effective, are, as has been seen, extremely costly, and can only be described as crude.

What is needed is a cheap method of treating breeding waters, possibly the slow and chemically regulated solution of some direct poison which will destroy either the larvæ, or associated organisms upon which their existence may depend. Much more water, and wider areas, could be treated than by present means, because they would require to be visited much less frequently, and the tendency would be for mosquitoes to die out of regions which were worked intensively. For the eggs necessary to start new broods

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

must come from adults, whose span of life and power of migration are alike small. In any case the insect's recruiting power would be lessened automatically and independently of accidental failure to carry out weekly oiling, and the victory achieved would be on the lines of the higher strategy, enabling a few trained operators, travelling from place to place, to do the greatest possible amount of good.

But the possible means of destroying mosquitoes, and their larvæ, are very varied, and what is wanted may in many cases exist free of all cost where it is most needed. Some years ago Sir Malcolm Watson suggested that the effect of contamination of mosquito-breeding waters by the waste products obtained in the process of rotting out fibres, etc., might be to check mosquito-breeding. Research fully confirms this supposition, and wide areas under rice in Malaya are practically free from anophelines owing to the presence of underlying peat. Methods of control which utilise not costly manufactured chemicals, but cast-away products of mining and of industry, should everywhere be tested. To the biologist it is almost unthinkable that mosquito larvæ could develop healthily in any highly mineralised water. Their vital adjustments are too delicate; and they, and the organisms upon which they feed or are in other ways dependent, are racy of the soil. The ultimate test of poisons such as these must be in the field, and in strengths which, with a margin of safety, will just destroy the broods before the adults hatch out. Laboratory experiments dealing with high concentrations of poisons, often dangerous to man, and which kill larvæ in a few hours, do not give all the information which is needed for the ideal process, which will work continuously and abolish mosquito-breeding with the lowest effective concentration of substances harmless to men and animals, and, if possible to fish as well. Nature does this in her biochemical laboratory everyday.

Waters of the most diverse kinds (waterfalls, cesspools, rain-filled tree-holes, and the accumulations in pitcher plants) abound with the larvæ of different species of mosquitoes. Why is this? It is notably true of individual species of the genus *Anopheles*. The larvæ of each species is found only in its own chosen types of water, and in its own favoured haunts, some in swiftly running streams, others in contaminated puddles, others again in the mere film of water which seeps from hillsides barred to the tropical sun, and yet others in the quiet darkness of the hollow centre of a bamboo, the only access to which for rain and mosquito alike is by the tunnel of a boring beetle. But what from the anti-malarial standpoint is even more suggestive is the fact that there are numberless waters, some small and precarious, and others permanent and of vast extent, where the most diligent search fails to discover a single larva. As every field worker knows, it is quite a mistake to suppose that most waters breed dangerous anophelines. The contrary is true, for, as we have just seen, each species requires its own peculiar water, and its own special environment. Moreover, wherever a survey has been carried on over a period of months it has been observed that the amount and character of mosquito-breeding fluctuates. How much would we not give to know the reason for the spring-time abundance of the oriental *Anopheles maculatus*, responsible for the May epidemics of malignant malaria in plantations in the hills of India, Ceylon and elsewhere? Is it due to some inherent trait in the mosquito, or to some small and controllable variation in the water, or to the prevalence in it at this season of a minute alga or infusorian, which provides nourishment for the larvæ, and whose inopportune entry upon the scene might, with a little more knowledge, be denied?

Since MacGregor first drew attention to the subject, the relation between the hydrogen ion concentration of natural waters and the distribution of anopheline larvæ has been the subject of enquiry in a number of countries. But there are other chemical factors calling for attention. Though in America Purdy has been unable to trace correlation between the distribution of anophelines in certain rice fields and the chemical constitution of their waters, as revealed by quantitative analyses, in Malaya the facts brought to light by Hacker, the full details of which have not yet been published, taken in conjunction with Blair's analyses go to show that the seasonal prevalence of *A. maculatus* is associated with various chemical factors present in its breeding water, which in their turn are related to rainfall; while more recently, both in Ceylon and Malaya, correspondences have been traced between the presence or absence of larvæ of particular species of anophelines, and the amount and nature of the substances dissolved in the water, especially those of organic origin. All this work requires to be repeated and greatly extended in the light of the experience already gained; for it opens up the possibility of entirely new methods of mosquito-control. Yet in most countries chemical research is not recognised as an essential part of anti-malarial investigation, nor conceded any claim at all to recognition.

Can this neglect, and the neglect of research in many other fields, where its usefulness is hardly questionable, be justified? While it continues we must not grudge the sanitarian and the anti-malarial engineer the prodigal sums they have to expend upon defensive measures limited to narrowly circumscribed areas. But properly directed research, by pointing the way to economy, must in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

end greatly extend the range of effective control over dangerous mosquitoes. It is not so much money as effective organisation, based upon realisation of the needs of research, that is wanted. We are therefore tempted to try and state our view of what these needs are, speaking primarily as biologists.

Justification of the biological outlook and the need for biochemical research.

Disregard of the biological outlook sometimes tends to false simplification of vital problems, but the malarial investigator is more often impressed by the numberless uncertainties and difficulties connected with his work; and, perhaps through imperfect acquaintance with the possibilities of biological research, even in its present stage of development, he is apt to acquiesce in its neglect.

The mosquito is thus relegated to the status of a *corpus vile*, to be slain with any empirically forged sledge-hammer that comes to hand, rather than regarded as an elusive entity, requiring profound and patient study for its management and mastery. And the same attitude of mind is shown, though with greater justification, in the neglect of the much more difficult field presented by the experimental study of the malarial parasites. But a science such as biology, which has already attained to the command of methods which have resulted in the chemical fertilisation of ova, the control of growth and development by endocrine feeding, and tissue culture, in diverse phyla of the animal kingdom, and which has demonstrated the dependency of the larvæ of the fly *Drosophila* upon a particular protein derived from yeasts present in the fruit they feed on, is justified in the hope that if it is given fair opportunity, it may contribute decisive aid to the suppression of insect-borne diseases. Merely empirical knowledge, however, is no longer enough. Complexities must be unravelled, and hidden causes must be traced and brought to light, with the help of every available refinement of technique.

It is desirable to recall that both logically, and probably also from the point of view of the ultimate eradication of malaria, the experimental investigation of the malarial parasites claims precedence over that of anopheline mosquitoes. But the physiological reactions of the parasites to drugs and other agents which may disturb their normal economy, complicated by interactions between the drug, if present, the parasites, and the tissues of the hosts, whether insect or man, constitute so formidable a group of problems that even their proximate solution will depend upon the progress of biochemistry. It may have to wait the development of a technique permitting the detection, if not the quantitative estimation, micro-chemically, of minute traces of the reacting substances, even the general nature of which is at present unknown.

The key to the control of mosquitoes as well as that of the malarial parasites must be sought in a knowledge of their normal life processes. Hitherto both anti-malarial therapeutics and measures for the destruction of mosquitoes have largely disregarded this truth, basing practice upon records of mere survival or death in the presence of drugs or larvicidal agents. Though justified by immediate expediency, this procedure promises neither complete practical success, nor the acquisition of ultimate knowledge of basal principles. And it is not in the full sense of the word scientific, for it builds up no interconnected body of knowledge. Through its neglect to seek out their causes, the phenomena recorded appear as isolated facts, and future investigation is left in doubt where to turn and what new practical expedients to test. It is therefore evident that the key to the control alike of the mosquitoes and of the malarial parasites is to be sought in a knowledge of their life processes; and until we understand these in their normal manifestation, we cannot attain to an understanding of the effects of destructive influences, nor increase their efficiency by combining or modifying them in accordance with already ascertained principles.

Turning to the anopheline mosquito, the investigation of its whole physiology from egg to adult is of first-rate theoretical importance. And many of the problems which present themselves for enquiry are also of immediate practical significance. The importance of bionomic studies defining the conditions of life suitable to different anopheline species has already been widely recognised. But the explanation of the connections, already observed or to be discovered, between anophelines and their food, or the chemical factors of their environment, is to be sought in a knowledge of their physiological and biochemical reactions: so that bionomic studies are strictly speaking less fundamental than physiological researches.

Not much need be said about the eggs of mosquitoes beyond pointing out that their powers of resisting solar radiation, desiccation, heat, and burial in mud, are all dependent upon innate physiological properties, including hygroscopic permeability, the need for oxygen, and permeability or impermeability to toxic substances such as poisonous gases or solutes, given off, or present in, the water or soil. The fact observed by Bacot, that the eggs of *Aëdes argenteus* (*Stegomyia fasciata*) are dependent for their hatching upon bacterial stimulus, also calls for physiological explanation. Investigation of the physiology of the adult mosquito is chiefly needed because it must sooner or later lead to an understanding of the supremely important

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

factors which permit the development of the malarial parasites in certain species only of anophelines, the ability of which to carry malaria seems to vary in different countries, and may be largely dependent upon environmental conditions. Even the possibility that there may be culicine mosquitoes whose digestive and body fluids resemble those of proved malaria carriers, and which are therefore themselves able to transmit malaria must not be entirely excluded.

The larval and pupal stages of development evidently possess a special practical importance owing to the comparative ease with which larvæ and pupæ may be located, and dealt with. As already suggested, in order to understand the mode of operation both of artificial larvicides and of natural agencies destructive of larval life, the normal physiological functions and requirements of each species of anopheline larva must be investigated. In the meantime the bionomic relation of larvæ of different species to their special environments requires much more detailed study than has yet been given to it, the chief points at present requiring elucidation being:—

1. The direct effect of elusive chemical factors, and of physical influences, such as the intensity and the quality of light radiations, upon larvæ in their natural habitat, and in the laboratory.

2. The influence which these factors exert indirectly, by acting upon the microbic, infusorial, and algal life of the waters, some of whose forms are beneficial, and others harmful, to mosquito larvæ.

The accommodation between one form of life and others is nowhere more finely adjusted than in natural waters. The balance may be upset by a hair-trigger, the lever of which is the micro-organism, broadly defined to include all categories, whether algæ, bacteria, or protozoa. By reason of the extreme tenuity of their exterior membranes, which are often less than one hundred thousandth of an inch in thickness, these organisms are much more susceptible to chemical influences than are mosquito larvæ themselves. Not only do some of them spread infectious disease (and the diseases of mosquito larvæ are an almost unexplored field of knowledge), but, as has been hinted, they may form an important part of larval food, as they, and the minute crustacea inhabiting both fresh-water lakes and the sea, do of the food of fish. The study of this floating life, or plankton, is a recognised department of fishery research, and its methods are as refined as the scale on which it is carried out is liberal, both far surpassing the wildest dreams of the anti-malarial investigator. One of the writers is glad to acknowledge his indebtedness to these researches and to the inspiration they have been to him, as well as to record his gratitude to the Royal Society for a small grant enabling him to become possessed of a single piece of specialised apparatus for water analysis, probably the only one of its kind used in anti-malarial research. By its aid several doubts have already been resolved. But who might not envy the equipment of, for example, the lake-side Laboratory of Wisconsin, which permits the collection of the most minute organisms in quantities sufficient to afford material for chemical analyses? These investigations have been extended, mainly in the spirit of pure research, to the fresh waters of Germany, Denmark, and the United States. In the British Empire enquiry is chiefly concerned with marine investigation, prompted by the desire to increase our food supplies. This aim is beyond cavil, but is it not at least as important to prevent sickness as to increase food supplies? It is of course only natural that the majority of anti-malarial workers, already overwhelmed by the ever-increasing volume of literature with which they must acquaint themselves, should have overlooked obscure but precious publications in the journals of marine and fresh-water biology. But it is a fact, the inner significance of which is rather puzzling, that while hard-headed business men, and cautious statesman, have for the past twenty or thirty years been convinced of the urgent practical need for studying the minutest microscopic details of the food of fishes, and have provided the money and the men to do so, the idea that any such need exists in connection with mosquito larvæ would probably be regarded as rather whimsical by many of those who direct anti-malarial research in the British Empire. But in the United States a plankton expert has for many years been investigating anti-malarial problems for the Department of Public Health.

Fortunately, given time, patience can overcome many of these difficulties at no cost at all. For by its method of feeding, the anopheline larva is the best imaginable collector of the surface plankton, though needless to say on a very small scale, too small to meet the needs of quantitative chemical work. Nevertheless, the contents of the larval stomach when isolated (no very easy matter in the case of young larvæ), and examined under a powerful microscope, reveal a treasure-trove, requiring all, and more than all, the knowledge that even a specially trained worker possesses, for the classification of its various constituents. Two or three hours may easily be spent upon a single larva in this way. The next step should be the cultivation, in pure strain, of judiciously selected samples of the organisms which the water contains, and the study of their effect, beneficial or the reverse, and especially perhaps of their nutritive efficacy, for various species of larvæ. Every bacteriologist

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

will realise the demands upon time and labour entailed by the care of an accumulating series of pure cultures, which have to be continually renewed if they are to be kept alive, and tested in the ever-varying conditions which may be suggested by the research in progress. The difficulties are tenfold increased, when, as in the case of many aquatic organisms, the conditions under which they will grow at all have to be the subject of preliminary, and often prolonged, investigation. With the present organisation of anti-malarial research in most countries, such work is all but impossible. For those who might undertake it are burdened with peripatetic duties, either administrative, or in connection with the collection of epidemiological data over wide areas. It is true that in India and in the more enlightened Colonies there are research institutes, and to the needs of these we will devote a few concluding words. But we have not yet quite done with micro-organisms as they affect the life of mosquito larvæ.

Their most potent influence is chemical. At least this is true of the bacteria and moulds which transform rotting leaves and other debris found in the water into soluble substances which have the profoundest influence upon larval life, absolutely inhibiting it in certain cases, or, as is more usually the case, rendering particular waters suitable for only a few specialised types of larvæ. Bacteria, besides being the arch-chemists, are the scene-shifters of Nature. Among innumerable other activities, they set and furnish the stage upon which mosquito larvæ play their part; and forbid them entry when the stage is set for others. Their indirect effect in favouring or forbidding the friends, or in fostering the foes, of larvæ, may in many cases be more potent than the direct influence upon larval life of the chemical substances which they fabricate. Although these substances are roughly classified by the analyst under such headings as "peaty acids," "albuminoid nitrogen" and other general categories, these names conceal an almost total ignorance of the inner constitution and intimate properties of the substances named. And these are what matter. For we are brought up against such facts as the occurrence of the larvæ of the Malayan *Anopheles umbrosus* in water impregnated by jungle peat, while it is absent from the equally, but differently, peaty water of certain rice fields. The whole process of leaf-rotting (and of rotting in general) therefore needs to be studied, both in its bacteriological and its chemical aspects, in order that the lessons learnt may be applied to the control of this and other dangerous species. Nor do bacteria confine themselves to the breaking up of organic substances. At one point in both the iron and the sulphur cycles, primitive types intervene, and effect the oxidation of poisonous ferrous salts, and of sulphuretted hydrogen, respectively, thus favouring, though not always achieving, the salvation of the larvæ. Nor are bacteria the only micro-organisms which are able to effect the transformation of iron. The possibilities which these and allied phenomena open out, of controlling mosquito-breeding over wide areas, and without recourse to expensive chemicals, surely justify their being studied in detail and being accorded recognition as legitimate departments of anti-malarial research.

Needless to say these investigations should not be carried out to the exclusion of the technical and highly skilled research required to elucidate the physiology and biochemistry of the different species of malarial parasites in relation to human immunity, the effect of drugs, and clinical conditions. And in entomology there will always be work for the naturalist bent upon bringing to light the instincts and manner of life of mosquitoes, and of their natural enemies.

The Organisation of Research.

Taking all these needs into consideration, and allowing due weight to the necessity for uninterrupted and continuous investigations, an institute for anti-malarial research must be amply staffed and adequately equipped, so as to provide for the carrying out of refined experimental as well as microscopical work. Work calling for specialised activity in half a dozen sciences cannot be carried out by only one or two men. This was just possible so long as field observations and the collection of epidemiological data constituted the main endeavour. But such work often entails long absence from a laboratory and is incompatible with protracted experimental researches, which require continuous attention. Therefore at least one epidemiologist skilled in spleen and blood work, and who in the natural course of things will be a medical man, must be included in the staff; at least one micro-biologist, an entomologist, and a research chemist able to isolate and elucidate the reactions of the numberless unknown compounds of organic origin which permeate natural waters. If in addition he is a trained biochemist this will be all to the good. All these categories of workers might properly be duplicated, especially in tropical countries, where ugly blanks in the continuity of experimental investigations are liable to occur owing to long absences on leave of those who have started them. Professor Warrington Yorke of the Liverpool School of Tropical Medicine, addressing the recent Imperial Entomological Conference, in reference to sleeping sickness, pointedly remarked:— "Even work admirably conceived is often brought to naught by the fact that those who are conducting it go on leave without arrangements being made to carry it on ..... the initial excellent

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

work is thus rendered useless, and knowledge, or shall I say ignorance, remains *in statu quo*." Even this degree of disorganisation, however, is infinitely better than for one or two men to spend their time rushing about, meeting urgent, or supposedly urgent, demands, under conditions which preclude all serious experimental work, and therefore all real progress. They probably earn their salaries, but not as research workers; and this is hardly honest towards the community which believes that it pays them for their skill in investigation, nor very fair to the men themselves. But in order to carry conviction on the main point we are content to state the minimum needed for carrying out anti-malarial investigation on anything like an extensive enough scale. And be it added that one or more of the most enlightened colonial Governments are providing the men, but the specialised and diverse training that they require is not always realised, nor is the bewildering complexity of the task that awaits them. We may therefore be pardoned if we labour this point a little further.

A single epidemiologist, concerned with routine blood and spleen examinations, will have little time for real research in his own subject, whether on biochemical or microscopical lines; but he should have the aptitude and training needed for this work, so that he may do it whenever the opportunity presents itself. The water chemist should, apart from ability to conduct preliminary routine analyses, be able and keen to investigate at least the proximate chemical causes of the total biological properties of the various waters in which mosquitoes breed. He should, for instance, be prepared to track down the particular acids and bases, either already known, or, for the most part, awaiting discovery, upon the presence of which their hydrogen ion concentration depends. For it is their precise nature, quite as much as upon the resultant reaction of the water, that probably determines the character of the microbial fauna and flora. And probably the particularities of the micro-organisms determine, at least in part, what, if any, mosquitoes will breed in the water. Here the microbiologist steps in to test each theory, and by the chemist's aid to regulate the equilibrium of life to the desired end, namely, the suppression of mosquito-breeding. The instructed reader will already have smiled at the word microbiologist. Outside the rank of writers of text-books (the best of them compiled by a syndicate of specialists), he hardly exists, even in name. And these text-books practically ignore aquatic organisms, most of which in the tropics are yet uncatalogued. Algæ are not mentioned in the standard works dealing with microbiology! In England if a man knows his diatoms he is, in his own purblind circle, respected. A mycologist is a mycologist, and does not lay claim to be a bacteriologist; and a protozoologist, able to deal with all comers among the riotous denizens of every disreputable pond and ditch, is not found in every university. As compared with routine bacteriology, that of natural waters, and of the soil they overlie (the microbically induced chemical changes in which appear to be most important in the case of peaty, and perhaps of ferruginous soils) deals with hundreds, if not thousands of species, instead of a few selected ones. How few of all these forms of life, it will be objected, can have any effect upon mosquito breeding! True, but that does not render the detection of those that have any easier. The difficulty is in the pounce, haling out the criminals, and putting in the way of wider well-doing those that already go about it unsuspected. But let us be contented with a microbiologist, a man with a plaguing pen, and the habit of sending out litle tubes all over the world to be christened by the orthodox Latin and Greek rites. Sometimes the two orthodoxies get mixed in the same mouthful, and then he has to send the hybrid cognomen to his classical friends for them to submit to the test of taste, and tell him what it is all about; but their replies may only darken wisdom. In the meantime he will be well content to call whatever it relates to X|231 of the something-or-other-*aceæ* and set to work with it, while preparing his mind for multi-partite fission in any direction at a moment's notice, at the call of the next emergency.

To save the entomologist from this fate, better befitting the microbic brain, there might be two of him, one dealing with all the problems of medical entomology, and especially all that concerns the minutiæ of the scores of species of mosquitoes found in tropical climes; while the other investigates the problems of general entomology which relate to the mosquito, such as those dealing with mosquito-destroying insects. This is an entirely practical suggestion, since many of these insects are extremely destructive to larvæ, and it should be possible under expert supervision to breed some of them such as "water-boatmen" in mass, and to stock such places as fish-ponds periodically with their eggs. These ponds are a pestilent source of annoyance, if not of malarial infection, in the Chinese quarters of some of the towns in Malaya, owing to the fish being either of the wrong kinds, or too well fed by their Chinese owners to make any impression upon the hosts of anopheline larvæ the ponds contain. Oiling is difficult, and seldom, if ever, attempted in these ponds; and there appears to be no reason, when the necessary knowledge concerning the breeding and acclimatisation of these insects has been gathered, why they should not be enlisted, and at the most trifling

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cost, to do the work that Nature herself has allotted them. But this would require the accurate adjustment of means to this end, and experience derived from long and careful observations. If the water to which they were transferred proved harmful to the insects the advice of the chemist might have to be sought: and if they sickened of fungoid or bacterial disease, that of a mycologist or a bacteriologist.

We have not yet enumerated all the branches of knowledge which the malarial investigator must lay under contribution. Who for example is to diagnose the mites which infest mosquitoes? And where is the botanist to be found with an intimate knowledge both of the local flora, and of the breeding places of local anophelines, who will be able to say at a glance whether this or that place is likely to be dangerous? For there is no doubt that there are plants which are useful indicators of calcareous, peaty, and other types of soil, associated with particular species of anopheline larvæ, and yet others which convey a warning that spots which happen to be dry at the time of inspection are liable to periodic inundation. A knowledge of this might prove valuable, both by saving time when making extensive field surveys, and by guarding against hasty and erroneous deductions. We confess that we do not know how, in a general way, these needs are to be met, nor how the rainfall and other necessary meteorological data are to be obtained when working at a distance from official recording stations, unless the malariologist steps into breach and does the work himself. From the standpoint of research this title is much too comprehensive. But we have no wish to exaggerate difficulties, nor to advocate narrow specialisation. A staff selected on the lines just laid down, even if every by-path cannot be explored, should be able to give a good account of the field of research as a whole. And there is a great deal to be said for companionship in research. For not only is the friendly criticism it brings a corrective to the extravagance and one-sidedness of ideas born in solitude, but intellectual comradeship puts heart into the lonely worker. He is cheered by hearing a new day, to be filled with rummagings of great price, proclaimed from another watch tower than his own. Anti-malarial investigation, perhaps more than any other, needs to be simplified by being shared, for it sometimes seems to stretch like a teeming and shelterless plain extending almost to infinity and requiring exploration in every direction.

In these few pages, the gleanings of a long correspondence conducted overseas, we have not been able to do justice to the work that is being done in various parts of the world, nor even to outline all the possible developments of anti-malarial research. In much of what relates to the properties and mode of action of oils on mosquito larvæ, as well as to the invisible chemical and heat rays given out by the sun, and modified by the atmospheric and other factors, help is needed from advanced physical and meteorological research. But we have said enough to show that if the work calling to be done is to be done properly, its needs must be more fully realised and provided for than has been the case in the past. No science includes so many other sciences as that of medicine; and medical men, besides following their own intricate lines of research with a versatility and devotion without parallel in any other profession, whenever the need has arisen, have done pioneer work in entomology, helminthology, protozoology, and other spheres of knowledge which throw light on tropical diseases. Nor, when convinced of the need, have they been slow to enlist the services of lay scientists, especially of entomologists, though far too few men and women with a thorough training in general entomology are at present working on medical problems. In other spheres, as the case already cited of the need for applying the methods of plankton research to anti-malarial investigation proves, whole departments of knowledge may remain neglected because unknown. We believe that the only remedy for this state of things is a general council of medical research, and one for anti-malarial research in particular, including the best and keenest representatives of *every* branch of science (even geologists and mining chemists, for example, should certainly not be excluded) as well as medical men. Illuminating ideas would be born of the conflict of opinion, and we should less often see the wrong men chosen, the right men thwarted, or technical problems being attacked by methods a quarter of a century old. That this is no exaggeration nor any reflection upon medical knowledge in particular is shown by the fact that botanists were content to magnify the growth of plants fifteen or twenty times until they were taught by Sir J. C. Bose to obtain a magnification of a million by methods familiar to every physicist for the last three or four generations. The facts revealed by this application of physics to the problems of botany were so surprising as to be positively disbelieved for a decade. What similar surprises, fraught with infinitely greater importance to mankind, may not await medical science?

This brings us to a final practical suggestion. The lot of the research worker in the tropics is apt to be discouraging. The conditions under which he works might sometimes be improved. He often feels that he is valued rather by the standards of routine, than by the worth of his contributions to knowledge, if indeed he has time to make any; and that while the talk of the shops, and all it means,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is denied to him, he is falling behind the times. Therefore the greatest good would follow from giving universal effect to the suggestion, recently made in connection with an Imperial Research Committee on our African Colonies, that British scientists should visit all Colonies and Dependencies every year. If the acknowledged leaders of science cannot always come themselves, let the keenest of the young men, themselves imbued with the spirit of research and familiar with its refinements, carry back their reports. They should, if possible, work along with those they come to help, even if only for a short time; for only so will they learn to appreciate their special difficulties and be able to form plans for removing them. They should constitute an informal liaison between the workers and the scientific authority at home after their return. While this would be their main duty, they would also be able informally to enlighten local authorities as to the value of the work being done, especially if this was on new and little understood lines, and to learn their views. Those thus visiting our Colonies would not be without the sense of good accomplished. Not only would their work be vital for science but vitalising, and its interest would be very great. For the tropics are so full of curious riches, especially in the biological realm, that any one working there can pass on material for investigation by the handful.

The need for more, and much more, knowledge of malaria, which we have ventured to urge, received somewhat striking confirmation while the foregoing paragraph was being penned. A very able malariologist, a medical man whose hobby is research, and who has had many years' experience of preventive work in rubber estates, remarked with just sufficient irony, that he had long ago given up considering malaria a preventable disease. At present, and not for the first time, his hospitals are filled, in spite of the fact that he knows every inch of the drains on his estates, and that he devotes much time to seeing that they are regularly, and if the word can be justified, scientifically, oiled. One knows these major and minor epidemics, many of which are never explained. This is not a satisfactory state of things. As already suggested the remedy is, by the acquisition of fundamental and not merely empirical knowledge of everything relating to malaria and the mosquito, to improve beyond recognition our methods of dealing with both.

In the meantime we must be content, until the dawn, to grope with the torch bearers. But let us be clear about what we should seek, and what are the moral pre-requisites of success. First and foremost is wanted a medicament, or a physiological or physical agent, which will utterly destroy the malarial parasite from off the face of the earth. That is the root of the matter. Secondly, means far more effective than at present exist of ridding ourselves of the mosquito. And, first and last, open-mindedness and generalship to permit, promote, and apply discovery. "The enthusiast," Sir Ronald Ross has remarked, "is rare: the successful enthusiast very rare." Those words convey a warning. For enthusiasm by itself is blind; and success in medical as in other investigations has in the past been determined, and must in the future continue to be so, by imagination, penetration, and sound inductive reasoning. The problem of the organisation of research is to secure their harmonious co-operation. Therefore, save by a miracle of pure intuition, there will be no millennium free from malaria, which is not the creation of thought, free to pursue its patient and sometimes painful progress through a bewildering nexus of facts, the discovery of which calls for labour no less painstaking and thorough. Thus only, like the brain itself, knowledge grows by the elaboration of interlacing strands, till, their circuit completed, light is kindled, to remain an inward possession and a lamp before men's feet.

Current Topics.

The Post-Graduate Hostel, London.

A NEW venture which will be of interest to many of our readers is the opening last July of a Medical Post-Graduate Hostel at the Imperial Hotel, Russell Square, London, W.C. 1. The objects of this Hostel are to provide a central hall of residence for medical men visiting London, a smoking and reading room and a recess in the dining room being reserved for their exclusive use: to promote the interchange of thought among medical men hailing from other countries: to encourage original ideas and work by means of informal discussions: to enable its residents and medical men in London to meet teachers from London, the provinces, and abroad in discussion: to further the work of all existing post-graduate institutions, especially the Fellowship of Medicine: and to foster imperial friendship. Amongst those on the committee of the Hostel are Sir D'Arcy Power, Sir G. Lenthal Cheatle, Dr. Alfred Cox and Sir Thomas Horder.

The Hostel is very centrally situated, being within 400 yards of the new home of the British Medical Association, and very close to many of the London hospitals; also within easy reach of the Royal Society of Medicine. The privileges of the Hostel are restricted to fully qualified medical practitioners, and informal evenings for discussion, special dinners, and social evenings are arranged. The terms at the Imperial Hotel are very moderate, and the Hostel is run by a committee of six *ex-officio* and two elected members, which include representatives of the British Medical Association, the Royal Society of Medicine, and the Fellowship of Medicine.

Many medical men from India visiting London will be glad to know of the Hostel. Full details with regard to it can be had on application to A. P. Bertwistle, Esq., F.R.C.S. Ed., 4, Spital Square, Bishopsgate, London, E.

The British Optical Convention, 1926.

A DELUSION which dies very hard with the medical profession is that British lenses and microscopes are

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

inferior to those manufactured on the Continent. This is not the case; in fact Great Britain leads the world in the production of optical glass and lenses. At the British Optical Convention held in July 1926 at the Imperial College of Science, South Kensington, there were many interesting addresses, and many important exhibits. The Convention was opened by the Prime Minister, Mr. Stanley Baldwin, and the presidential address was delivered by Sir Frank Dyson, F.R.S., Astronomer Royal of Great Britain, whilst among the Vice-Presidents present were Sir Ernest Rutherford, Sir Oliver Lodge, Sir William Bragg, Sir Ronald Ross and Sir Richard Glazebrook. The Proceedings of the Convention, containing verbatim reports of the papers and discussions, have since been published at a cost of 30*s.* 6*d.* (including postage); and also an illustrated Catalogue of the Exhibition, which contains a full account of up-to-date British optical instruments, including cameras and photographic lenses, microscopes, spectroscopes, colorimeters, spectacles and optical instruments, etc., at a cost of 6*s.* 9*d.* (including postage). Both are available from Mr. Thomas Martin, Secretary to the Convention, 1, Lowther Gardens, Exhibition Road, London, S.W. 7; and many of our readers may be interested in these publications.

From the published account of the Proceedings we take the following items, which will be of interest to our readers:—

"The Astronomer Royal, in his presidential address reviewed the progress of optical manufacture in Britain and added some remarks on the contributions of astronomers to the art of optical design.

From about 1848 to the early 'eighties England occupied a dominating position in the manufacture of optical glass, but the challenge of Jena produced a temporary eclipse of such importance that in 1912 Britain imported 60 per cent. of her glass from Germany, 30 per cent. from France, and made only 10 per cent. at home. The outbreak of the war revolutionised this situation. The Institute of Chemistry initiated research upon glass manufacture so successfully that by 1917 the required formulæ had been found and, thanks mainly to the work of Sir Herbert Jackson, adequate supplies were made available for Britain and her allies. In 1918 nearly 9 tons of optical glass were being produced per month, and opticians can now obtain from British sources all the glass they require.

The war also led to great developments in range-finders, which find a use in peace-time for surveying and navigation; in lenses for aerial survey, and other instruments. British-made prismatic binoculars, which before the war were inferior to those from Germany, now hold their own with any in the world (and in particular offer a wider angle of view than any others).

The present progressive state of optical manufacture in Britain may be attributed to improved facilities for technical education, particularly at the Imperial College of Science; to the research and testing work carried on at the National Physical Laboratory, which supplies a constant stimulus to a high standard of achievement; to the Optical Society, which brings together manufacturers, theoretical opticians, astronomers and physicists; and to the British Scientific Instrument Research Association.

Turning to his own branch of science, the Astronomer Royal mentioned that a British worker, Gascoigne (who was killed in the Battle of Marston Moor in 1646), first invented the use of cross-wires in the telescope. The achromatic objective was due to another English scientist, Dollond, and the manufacture of these lenses became a British monopoly until it was killed by the glass tax. The removal of this tax in the middle of the 19th century led however, to a revival of the industry. Telescope objectives increased in size until a 40-inch glass was made in 1897; and a 41-inch objective, an entirely British product, is now being made for the Russian Government.

As regards reflecting telescopes, Sir Isaac Newton shewed how to grind mirrors for this purpose; Hadley introduced the parabolic figure; Herschel made enormous improvements in the general design of the instruments; and Dr. Common and Sir Howard Grubb developed the silvered glass mirror. The lenses employed for stellar photography in England, the United States, South Africa and Australia are of British manufacture; and an amateur astronomer, Franklin Adams, having commissioned an English optician to design a suitable lens, has photographed the whole sky in 206 exposures, shewing stars one million times as faint as those of the first magnitude.

The development of the spectroscope owes much to Huggins and Lockyer in England, while the echelon spectroscope is made only in this country."

The situation with regard to British optical glass is well-expressed in the following extract from a leading article in *The Times:* "That good optical glass is not made in this country is a delusion which dies hard. At one time there was some justification for the belief, but it was true of other countries as well. . . . . Before the war more than half the optical glass used in this country came from Germany, less than a third was supplied by France; and the small residue was made at home . . . . . By the end of the war, though our consumption had increased more than sixfold, practically the whole of our requirements were being supplied from home sources. The manufacturing resources thus established remain in existence, and the continuous improvement of the technical quality of the products is ensured by a research association organised under the auspices of the Department of Scientific and Industrial Research. But these resources and the fruits of research will alike go for nothing unless the public make up their minds to buy British-made glass and the instruments in which it is employed. That in doing so they will suffer no disadvantage in respect of quality . . . . . is attested beyond dispute by Mr. F. E. Smith, the Director of Scientific Research at the Admiralty, in the letter which we publish to-day. The British Navy is the largest user of high-grade optical glass and instruments in the world, and in its contracts the Admiralty now specifies, as it did not before the war, that its optical stores shall be throughout of British manufacture. The requirements of the Navy are of the most exacting character, and what is good enough for the ships of the fleet must be good enough for the ordinary user. It is hoped, therefore, that the myth of the inferiority of the British optical glass is finally exploded."

Recent Improvements in Microscopes.

"Recent British developments in the design and use of the microscope were fully illustrated, in the instruments and apparatus exhibited.

A microscope has three main elements: the illuminator; the object glass; and the stand which holds the optical parts and object in their proper relative positions. Each of these elements is important, and in all three very notable advances have been made. A series of apochromatic object glasses is now provided, which are superior to any made in any foreign country; many of those doing the most exacting microscopic work are discarding the foreign lenses in favour of these new ones.

The important British work on filter-passing micro-organisms—"filtrable viruses" as they are called—demanded an accuracy of focussing and a rigidity which was not provided by any existing stand, and such a stand has now been evolved in Great Britain.

The improvements in illuminating systems are, if anything, more important even than those in object glasses. A dark-ground illuminator has been developed which permits the use of higher powers than heretofore. Almost immediately this resulted in valuable new knowledge of the structure of the micro-organism associated with a prevalent disease. Other new illuminators for opaque objects, including one peculiarly valuable for metallurgical specimens, have increased the efficiency of the chemical and metallurgical applications of the microscope.

One may mention the entirely novel combined illuminator used in very important recent investigations, in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

which a high aperture dark-ground illuminator is mounted concentrically with and encircling a quartz condenser. The former secures visibility, and is used to locate the micro-organisms, while the latter is used with ultra-violet light to secure the image on the photographic plate.

This is, perhaps, a favourable opportunity for pointing out how essential to medical research is an efficient optical industry. Adequate instruments for investigations on filter-passing bacteria were a year or two ago not in existence. The British investigators in this line of work knew the limitations of their apparatus, and knew just what their requirements were. They laid their knowledge and requirements before the instrument-maker, and in a comparatively few months were supplied with the instruments that enabled them to go forward and to obtain, among other important results, those very striking ones relating to the cancer germ, which were so much noticed in the press a short time ago. Most of the instrumental essentials for that recent successful work are British, like the work itself.

The Ophthalmic Section at the Optical Convention.

Over 30 exhibits of an ophthalmic nature were included. They were visited by a considerable number of the 8,000 or more people who attended the Convention.

During the period which has elapsed since the last Convention in 1912 great strides have been made in the ophthalmic-optical industry, and these were clearly revealed. Firms established within the past few years showed products of undoubted excellence which have not only found a ready sale in this country, but have also found a demand in foreign countries.

Ophthalmic lenses of all types, including special forms of bifocals, trifocals and protective glasses; gold filled spectacle frames made by the latest mass production methods, some of which are the result of individual research; ophthalmic instruments, cases, books and sundries were exhibited. The varied nature of these products proved conclusively the healthy and vigorous nature of the industry. As a result of their participation in the Convention a number of firms reported satisfactory business; and the manufacturers were unanimous in expressing satisfaction with the results.

Meetings of the Convention revealed the large amount of research work which has been carried out by ophthalmic opticians during the past few years. Two lectures especially, by Messrs. Owen Aves and W. Swaine respectively, dealt exclusively with statistical research, and they advanced many new and valuable points. Other lectures dealt with such varied subjects as visual accommodation and facial asymmetry. Professor G. Elliott Smith delivered a highly impressive address on the eye and its functions. The international reputation of this lecturer was upheld by his lecture, which was attended by a numerous company.

Although for many years high-grade optical glass had been manufactured in Great Britain, it was not until 1919 that the manufacture on a large scale of ophthalmic lenses was set on foot. The success which has attended this undertaking during the few short years of its history was amply demonstrated.

In the design of ophthalmic lenses remarkable advances have been made. To a wide range of invisible fused bi-focal (two-sight) spectacle lenses have been added tri-focal (three-sight) lenses, which involve complicated processes. Research work, which has been patiently and persistently carried on by experts in this highly specialised branch of work, has resulted in the production of unique lenses which eliminate many of the defects hitherto attaching to ordinary lenses. The practical elimination of chromatism (colour) from two-sight lenses, and the lessening by a considerable amount of the distortion produced by the older forms of lenses are two of the remarkable achievements which stand to the credit of this undertaking.

In one factory alone 25,000 square feet of floor space is filled with specially designed machinery working at full pressure supplying the growing demand for high-grade ophthalmic and precision lenses. Here is an instance where mass production has been reconciled with first-class work and unfailing accuracy."

The Office International d'Hygiene Publique.

AT the October 1925 session of the Office International d'Hygiene Publique in Paris representatives from thirty-three countries were present, the representative for India being Colonel J. B. Smith, I.M.S., (retd.). One of the most important matters dealt with was the question of an international code of nomenclature of causes of death; such a code was published in 1924 but has so far been adopted only by Great Britain and the United States.

With regard to different diseases it was recognised that deltaic Bengal is still the chief focus for cholera in the world. The Government of India reported that most vigorous steps were being taken,—at first on an experimental scale. In a selected area anti-cholera vaccination is being tried on an extensive scale under the auspices of the Indian Research Fund Association in order to study the results. Steps are also being taken to vaccinate the pilgrims to the Hedjaz. With regard to plague, reports were received from several countries—including India—on the distribution of the rodent fauna in these countries and the species of fleas prevalent on them. Australia, South Africa, Greece and Italy are taking special measures against the importation of infection.

A project for a co-ordinated enquiry into the pathology and prophylaxis of small-pox was discussed and several reports on small-pox, vaccinia, and alastrim, received from Great Britain, India, and Belgium will be published. A study of the incidence of tabes and of general paralysis of the insane in England has shewn that of 100,000 individuals with syphilis treated by the novarsenobillon derivatives only 10 developed these diseases, and it would appear that the introduction of the arsenical compounds in the treatment of syphilis is leading to a marked diminution in the incidence of tabes and of general paralysis. Further investigations on this matter are called for, however, since such factors as race, habits of life, and climate may affect the incidence. With regard to scarlet fever there has been a special study of the bacteriological aspects of the disease: Gabritchevsky's vaccine, the value of the Dick test, and the use of the sera of convalescents has been studied. Terminal disinfection in this, as in other, diseases is a most important prophylactic measure.

A special report was received on the new 1925 legislation in Great Britain on therapeutic substances. The regulations in different countries with regard to biological products and the arsenobenzene derivatives vary; some countries insist on an official testing of all batches produced, others leave the responsibility of testing to the chemical firms concerned. The Committee decided to carry out a comparative study of the legislation concerning this subject in different countries and to make a special report for study.

Other matters discussed were the international opium situation, the diseases of the Mediterranean basin, spirochætal and other forms of epidemic jaundice, the role of railways in disseminating disease, scurvy, the public health organisation in Egypt, and the results of the campaign against syphilis in Algiers.

The Physique of Indian Races.

AN interesting set of tables of heights, weights, etc., of Indian assured lives has recently been published by the Oriental Government Security Life Assurance Co., Ltd., Oriental Buildings, P. O. Box No. 148, Bombay. The tables are based on measurements of 3,439 Hindus living in Bengal, 18,006 Hindus in Bombay, 12,077 Hindus in Madras, 4,011 Hindus in the Punjab and Sind, 4,263 Hindus in the United and Central Provinces, 2,374 Mahommedans, 2,367 Parsis, and 4,649 Indian Christians. The conclusions drawn from a study of the tables are as follows:—

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

"The arrangement of the tables in the pamphlet is from the lightest average physique to the heaviest average physique, the lightest being the average physique of the Hindu of Bombay, Deccan and Gujerat, and the heaviest being that of the Hindu of the Punjab, Delhi Province and Sind.

From a comparison of the tables it is seen that the Hindu of the Punjab has the best all-round physique and comes nearest the European standard, followed by the Mahommedan, the Hindu of Bengal and the Parsi. The Hindu of the Central and the United Provinces is heavier than the Parsi at the lower ages, but at ages over 35 the latter becomes heavier than the Hindu and gradually draws away until a very marked difference in weight is observed at the higher ages.

There is little difference between the Hindu of the Central and of the United Provinces and the Hindu of Bengal, but it is observed that at ages above 35 the Hindu of the Central and of the United Provinces is of a remarkably good build, if short in stature, but he does not maintain anything like the same standard at the higher statures, while the Hindu of Bengal is rather inclined to obesity at the higher ages.

The tables for these classes were however based on a considerably smaller number of lives than were the tables for the Hindu of Southern India and Western India, but nevertheless it is believed that they reflect accurately the average physique of the class of people in the territories referred to.

The tables of chest measurements disclose the fine physique of the Parsi and the Hindu of the Punjab as compared with that of the other classes, the chest measurements of these classes showing a greater increase in relation to height than in the case of any other of the classes investigated. In these tables of chest measurements the Hindu of Madras shows up the worst of all the groupings investigated.

With regard to chest expansion, for men up to 5 ft. 7 in. in height the average chest expansion may be taken to be 2 in. for all ages and in the case of men of greater height the average expansion varies from 2¼ in. to 2½ in. The Parsi and the Hindu of the Punjab show the best chest expansion.

A comparison of the average abdominal measurements shows what was to be expected, that the difference between the average abdomen and the average chest slowly narrows down with the increase in age. At the older ages the abdominal measurement is almost the same as the chest measurement, but in the case of the Hindu of the Punjab the abdominal measurement tends to exceed the chest measurement at the higher ages."

The following table shows the average height of the individuals included in the various groupings as compared with the average height of Scotsmen, Irishmen, Englishmen and Welshmen.

	Ft.	In.
Scotsman	5	8¾
Irishman	5	8
Englishman	5	7¼
Welshman	5	6½
Punjab Hindu	5	6
Indian Christian	5	6
Parsi	5	5⅔
Mahommedan	5	5⅔
Bengal Hindu	5	5½
C. P. and U. P. Hindu	5	5⅓
Madras Hindu	5	5
Bombay Hindu	5	4

Statistical Studies on Heart Diseases.

AN interesting report on the statistical classification of cases of heart disease is one published by Dr. A. E. Cohn of the Hospital of the Rockefeller Institute for Medical Research, New York, and Dr. J. Wyckoff and C. Lingg in the *American Heart Journal* for 1926, (Vol. I, No. 4). The authors studied one thousand cases of heart disease admitted either as private ward patients or general in-patients, or studied as outside private cases of different races in the United States. Their conclusions are perhaps hardly applicable to Indian conditions, but it would be of considerable interest to compare their conclusions with a similar study carried out in the tropics. The author's summary of their findings is as follows:—

"In the foregoing analysis of 1001 cases of organic heart disease among adults, we found that:

1. There was a close resemblance among the histograms representing the three prominent types of heart disease for the clinic patient, private patient, and ward patient groups.

2. About one-fourth of the cases presented rheumatic heart disease, about two-fifths arteriosclerotic, about one-tenth syphilitic, and about one-tenth heart disease of unknown origin; other factors, such as scarlet fever, hyperthyroidism, nephritis, etc., together, comprised less than one-tenth of the total sample.

3. A comparison with the mortality curve led to the belief that the private and ward groups were more representative of organic heart disease, so far as age and etiology are concerned.

4. Rheumatic heart disease was rare after fifty years of age; from 90 to 95 per cent. of the cases of rheumatic heart disease occurred before the age of fifty years, more than half of which occurred before the age of thirty. About 50 per cent. of the syphilitic cases occurred before the age of fifty, and 50 per cent. after this age; the disease appeared to be rare before the age of forty and after the age of sixty. From 80 to 95 per cent. of the cases of arteriosclerotic heart disease occurred after fifty years of age. Two-thirds of the cases of unknown etiology presented lesions typical of rheumatic heart disease, and occurred before the age of fifty.

5. In about three-fourths of the cases of rheumatic heart disease rheumatic fever, either alone or in combination with other infections, was an etiological factor; tonsillitis, in one-fourth of the cases; chorea, in a little more than one-tenth of the cases, and growing or joint pains, in about one-twentieth of the cases. With the exception of chorea, which occurred twice as often among females as males, the relative frequencies of these infections was about equal for the sexes.

6. Rheumatic heart disease seemed to be as common among males as among females. In syphilitic heart disease the ratio of males to females was about seven or eight to one; arteriosclerotic heart disease appeared to be much more common among males than among females. The reason for this is inexplicable since the mortality from heart disease is about equal for the sexes in the higher age groups.

7. Foreign-born whites made up almost half of the total sample. Little could be learned about the predominance of race or nationality in any of the types of heart disease, both on account of the small number of cases, and because of the fact that age and etiology seem to be so closely related, and that the older immigrants, the Irish and the Germans, constitute the older age groups, and the newer immigrants, the Italians and the Hebrews, the younger age groups. With these points in mind, the rather large proportion of Irish found in the rheumatic group, the rather large proportion of Irish and colored, and the small proportion of Hebrews in the syphilitic group, and the relatively large proportion of Hebrews in the arteriosclerotic group suggest that a detailed study, comprising a larger number of cases, along this line is desirable.

While it must be strongly emphasized that no conclusive deductions can be drawn from the foregoing analysis on account of the small number of cases, this study should, nevertheless, focus attention upon the following points:

1. The available mortality statistics for organic heart disease are inadequate in any attempt to study the age incidence and duration of the disease, because they are based on deaths recorded in accordance with the International List of Causes of Death which is not so classified as to make it possible to distinguish between the infectious and degenerative varieties of the disease.

A NOTE OF WARNING!

DOUBT having been expressed by a medical practitioner in a recent issue of the *B.M.J.* as to the efficiency of Dimol when taken in the form of pulverettes, we desire once more to call attention to the fact that, where there is a deficiency of pancreatic enzyme, all keratin-coated tablets or pulverettes are liable to pass undissolved throughout the intestinal tract.

For this reason, and at the suggestion of various correspondents, sugar-coated B Dimol pulverettes (yellow) have been prepared and are found to give most gratifying results. They are partially dissolved in their passage through the stomach, but the action of Dimol is not impaired thereby, and is free to exert its powerful influence immediately after its passage through the pylorus; whereas the keratin-coated A Dimol pulverettes (white), even under the most favourable conditions cannot be expected to get to work so quickly, and may even, as above explained, pass undissolved.

Each pulverette contains 1 gr. pure Dimol, and Dimol is guaranteed by the Rideal-Walker test to be 35 times more efficient as a bactericide than carbolic acid; that is to say, in administering 3 Dimol Pulverettes, the patient is receiving the bactericidal equivalent of 105 grains of carbolic acid. Moreover, it is not absorbed, being voided with the fæces after doing its work.

When we are able to repeat this dosage four or five times a day without affecting the appetite or digestion, and without action on the mucosa, we can readily understand the excellent results which are obtained by the administration of Dimol in the treatment of auto-intoxication due to intestinal putrefaction, non-amœbic dysentery, rheumatoid arthritis, acute and chronic colitis, acute gastro-enteritis and intestinal fermentation.

2. By introducing into clinics a uniform system of records and organizing clinics in such a way as to facilitate the collection of facts for statistical purposes, reliable and important data concerning heart disease may be made available.

3. It is only when heart disease is treated in special cardiac clinics or wards or by physicians who are specialists in heart disease, and when these agree upon uniform methods of seeking, describing, and recording the facts as they present themselves in individual cardiac cases, that sufficient data can be collected and any progress be made in understanding the problems with which this study deals."

Reviews.

MOSQUITO REDUCTION AND MALARIAL PREVENTION.—By J. A. Crawford, M.B., Ch.B. (Edin.), Capt., R.A.M.C., and B. S. Chalam, L.R.C.P. & S. (Edin.), L.R.F.P. & S. (Glas.). Calcutta: Oxford University Press, 1926. Pp. 102. Price, Rs. 3.

THIS little handbook is designed, the authors say, to quicken the interest of the tea garden manager, the malarial inspector and the N. C. O. in charge of a sanitary squad in mosquito reduction and malaria prevention, and it must be reviewed in the light of that intention, or rather, let us say more generally, as a work composed for the intelligent layman.

There is certainly much in it that such a reader will find of much interest and pleasure, the latter due largely to its concise composition and first-rate production by the publishers. The principles involved are clearly stated, and the general classification and description of the mosquito life-cycle as well written as anything one could find anywhere.

At the same time though the book is written for the layman we think that "scientific" accuracy should not have been sacrificed in any particular. It may be true from a "practical" point of view that there are but 9 abdominal segments in the mosquito, but morphologically there are 10. Perhaps the best thing would have been to say "there are 8 visible segments." There are other similar inaccuracies in the book.

There are yet others which are of practical importance, e.g., on page 35 *A. listoni* is stated to have 6 pale fringe spots. Surely if the layman is to learn his mosquitos he should be told accurately how to do so. Similarly there should be no important omissions in their schedule. The book is addressed to tea planters, and yet no mention is made of *A. umbrosus* and *A. aconitus*, two species out of the 6 which particularly affect them, as Strickland has reported in the *Indian Medical Gazette*, Vol. LX.

In the section on the habits of mosquitos there are on pp. 47 and 50 some statements which may turn out to be true, but for which there is at present no evidence but surmise.

A handbook of this nature is certainly wanted nowadays for the purposes announced by the authors, viz., to stimulate the interest of the layman or unqualified man in antimalarial work.

MIND AND ITS DISORDERS.—By W. H. B. Stoddart, M.D., F.R.C.P. Fifth Edition. London: H. K. Lewis & Co., Ltd., 1926. Illustrations 87 including 6 coloured plates. Demy 8vo. Pp. xx plus 593. Price, 21s. net.

THE psychiatrical world, certainly the English-reading portion of it, will welcome the latest edition of what is becoming rightly one of the "classics" on mental disorders. Dr. Stoddart is to be congratulated not only on his book reaching its fifth edition, but on its containing to maintain its high standard of excellence. The whole work has been thoroughly revised and the following are the principal changes consequent upon such revision. The critical digest on intrathecal medication which the author included in the fourth edition under the heading of treatment of general paralysis, has given place to descriptions of two more recent and more successful methods of treatment, viz, the tryparsamide and malarial. Another change is the addition of a short—too short, some will consider—chapter on encephalitis lethargica. The chapter on the insane and the law—always melancholy reading—has been revised by Mr. W. H. Gattie, K.C. For the increase in the reliability of the index the reader will wish to follow the author's example and tender his thanks to Mrs. Stoddart.

DISEASES OF THE NEW-BORN.—By J. A. Foote, M.D. London: J. B. Lippincott Co. Illustrated. Pp. 231. Price, 21s. net. Obtainable from Butterworth & Co. (India), Ltd., P. O. Box 251, Calcutta. Price, Rs. 15-12 net.

THIS little book of 231 pages consists of a series of monographs from the pens of some seven professors of the faculty of medicine of Georgetown University. The whole are collected together by Professor J. A. Foote, the Professor of Pediatrics and diseases of children in the University of Georgetown, who has written the majority of the papers himself.

The first part of the book deals with the care of the newly-born child; describes the injuries and accidents which may occur to it during birth; and the proper treatment of such injuries. There is a special chapter devoted to intracranial hæmorrhage, and the author has given us an excellent description of the signs and symptoms of this serious accident. He asserts dogmatically that the best treatment of this condition is rest, quiet, the avoidance of all but the most essential movements and external stimulus. In this we are wholeheartedly in agreement with him.

Later on there is a description of the skin diseases of the newly-born, which is illustrated with some excellent photographs, and there is also a well written chapter on the problems of breast and artificial feeding.

The latter part of the book deals with statistics of infant mortality, and descriptions of such therapeutic measures as circumcision; how to irrigate the conjunctival sac; how to pass a catheter, etc., which appear to us to be somewhat unnecessary in a volume of this nature.

Though this little book contains practically nothing that is new, it is well written and compiled, and illustrated, and will undoubtedly be of use to the busy general practitioner who does not wish to go to the expense of a large text-book on the subject of pediatrics.

H. E. M.

AIDS TO PATHOLOGY.—By Dr. Harry Campbell, M.D., B.S. (Lond.), F.R.C.P. Fifth Edition. London: Bailliere, Tindall and Cox, 1926. Pp. viii plus 250. Price, 4s. 6d. net.

THIS little book will be especially welcome to medical students and to those reading for examinations. The new edition has been almost entirely re-written and contains much new matter, especially in the sections on the vitamines, endocrines, the spleen, diabetes, tumours, and immunity. The publishers are to be congratulated in having secured so well known a teacher as Dr. Harry Campbell as author of this volume of the "Aid Series." By the use of sections in small print an immense amount of information is included in the book. We can cordially recommend it to students, and to practitioners who wish to revive their knowledge of pathology.

AIDS TO CASE-TAKING.—By H. L. McKisack, M.D., F.R.C.P. (Lond.). Second Edition. London: Bailliere, Tindall and Cox. Pp. vii plus 168. Price, 4s. 6d. net.

"THE object of this little book" writes the author, "is to assist practitioners and students to examine their cases in a methodical manner. The ordinary syllabus

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of case-taking is amplified into a short manual, which is not restricted to a description of the methods to be adopted in examining the patient, but also indicates as concisely as possible the diagnostic value of the morbid conditions observed. Only those methods of examination are fully described which may be carried out in the practitioner's study, or in the ward or clinical room of the hospital."

In these objects the author has succeeded admirably, and this little book will be of value not only to the medical student, but also to the medical practitioner. Systematic case-taking is the very basis of modern medicine, and is a subject in which medical students in India should receive special training, since so often they tend rather to memorise from text-books than to learn real clinical medicine. The sections on examination of the blood and urine are good, and recent simple biochemical tests are described. The new edition has been largely re-written.

BAILLIERE'S NURSES' COMPLETE MEDICAL DICTIONARY.—By H. Clifford Barclay, M.D., F.R.C.S.E. Third Edition. London: Bailliere, Tindall and Cox, 1926. Pp. viii plus 248. Price, 3s. 6d. net.

THIS is a most handy little book and admirably covers the ground intended. It will be very useful not only to nurses but also to medical students and to junior medical practitioners. The indexed matter is full and is dealt with in simple terms. Appendices at the end deal with abbreviations used in prescription writing, initials used for degrees and diplomas, weights and measures, and the symptoms and treatment of cases of poisoning. Altogether an admirable little book, and one which would be very useful to readers in India.

"DAMPATI": A BENGALI BOOK ON MARRIED COUPLE.—By Dr. Sisir Kumar Sen, B.A., L.M.S. To be had from 75-1, Beadon Street, Calcutta. Pp. 143. Price, Rs. 2-8.

THE author has very carefully dealt with the subject of sexual science in dignified language. His intention is to elevate the morals of his readers and to instruct them how to be happy and healthy. There are very few Bengali books dealing with eugenic development and the author is to be congratulated for ably bringing this out. The book is to be recommended to all Bengali married couples.

CORRIGENDUM.

At the end of the review on p. 631 of our issue for December 1926, for the initials W. L. H. please substitute the initials H. G. A. Dr. Lilienthal's *Thoracic Surgery. The Surgical Treatment of Thoracic Disease* was sent to Lieut.-Col. W. L. Harnett, F.R.C.S., I.M.S., for review, but was subsequently made over to Major Alexander, I.M.S., for review; whence the mistake, which is much regretted.—ASSIST. EDIT., *I. M. G.*

Annual Reports.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF ASSAM FOR THE YEAR 1925. BY MAJOR T. D. MURISON, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, ASSAM. SHILLONG: ASSAM GOVERNMENT PRESS, 1926. PRICE 12 ANNAS OR 1*s.* 6*d.*

Food Prices.—The price of common rice was slightly higher than during the previous year; 9 seers to the rupee was the average price.

Birth and Death Rate in the Plains.—The former showed a decrease during the year, but it was higher than during the last quinquennial period. Compared with the birth-rates in other provinces in India, it is distinctly low, only Burma and the North West Frontier Province having a lower rate. The death rate has decreased markedly; it was only 22.52 per thousand, against 27.3 and 29.3, respectively last year and during the last quinquennial period. The lowering of the death rate was noticeable throughout the province. This was partly due to the better meteorological conditions and probably partly to the extensive kala-azar treatment campaign. Over 60,000 cases were treated; if these had not been treated a 90 per cent. death-rate amongst these might have been recorded. The deaths registered during the year numbered 187,127; an addition of over 50,000 to this figure would have increased the death rate up to that of the last quinquennial period.

In the Khasia and Jaintia Hills there was no epidemic of note and the birth and death rate underwent little change. In the Naga Hills registration is confined to a small area; as in the previous year, the death rate exceeded the birth rate. General health in the Lushai Hills was better this year. The registration in the Garo Hills district was extended to the hill portion of the district during the year. The birth-rate exceeded the death-rate in this district. The main causes of death were kala-azar and malaria.

There was practically no influenza during the year.

Deaths from cholera were returned as 0.9 per mille; this was considerably less than the decennial average. The district of Nowgong suffered most from cholera during the year. The disease broke out twice in epidemic form in Nowgong and affected almost the whole of the district, especially the areas adjacent to the banks of the Kallang river and also an area in the north-west of the district. The first outbreak occurred in June and July and the second one from October to December. Both epidemic units, consisting of 6 sub-assistant surgeons and 13 disinfection carriers, were employed under the supervision of the Assistant Director of Public Health, Assam. The special feature of the preventive measures undertaken was the inoculation of all contacts with cholera vaccine. This had a marvellous effect in arresting the disease. All sources of water supply were disinfected with bleaching powder and potassium permanganate. Certain streams from which the people of the infected villages drew their water supplies were infected and this rendered preventive measures very difficult. Under these circumstances inoculation proved to be the mainstay and was of the greatest value.

The epidemics in Darrang, Kamrup and Sylhet which were not so virulent responded to inoculation and disinfection of water supplies.

A total of 1,03,930 c.c. of cholera vaccine was issued during the year, of which 22,310 c.c. was supplied to local and municipal boards. The initial information as regards outbreaks of cholera now reaches the department much earlier, and consequently it is now possible to undertake preventive measures much more promptly. The rules regulating the system of reporting epidemics are now under revision in order to make them more effective.

During the year two epidemic units, each consisting of three sub-assistant surgeons and six disinfection carriers, were sanctioned for dealing with epidemics. They were of the greatest value in fighting epidemics, especially cholera. Two units have proved to be quite inadequate, and proposals for increasing their number are under consideration.

Red Cross pamphlets on cholera, dealing with the method of the spread of infection and how best it can be avoided were obtained and distributed. Magic lantern demonstrations with suitable slides were also given by the assistant surgeons on *kala-azar* duty. These pamphlets are also being read in primary schools, where they will have a far-reaching effect.

Amongst towns, Goalpara (2.09), Nowgong (1.59) and Karimganj (1.09) recorded high death-rates from cholera. None of them has a controlled water supply and it is probable that infection from the neighbouring rural areas was introduced into them.

Small-pox.—The death rate from small-pox was 0.4 per mille. This is almost the same as the decennial

Schering

VERAMON

Relieves pain without producing sleep

Consequently it should not be regarded as a hypnotic or narcotic, since it stands in a class entirely apart—a pure analgesic.

Clinical evidence refers to its successful employment in **Headache, Toothache, Neuralgia, Dysmenorrhoea, Otalgia,** etc., etc.

Original packing:—Tubes of 10×6 *grs. Tablets and in bottles of* 1 *oz. powder.*

MEDINAL

The well-known readily soluble **Hypnotic** and **Sedative** with no cumulative effects.

Indicated in **Hysteria, Dementia, Melancholia,** and **in the treatment of Morphia habit.**

Original packing:—Tubes of 10×7½ *grs. Tablets and in bottles of* 1 *oz. powder.*

ARCANOL

An efficient agent for the abortive treatment of Influenza and affections caused by chill.

The most important properties of Arcanol are those of an **Antipyretic, Antiphlogestic,** and **Antiseptic.**

Indicated in all diseases produced by **chill, catarrh of the upper respiratory tract.**

Original packing:—Tubes of 10×15 *grs. tablets.*

For Clinical Samples with Literature apply to our Representative in India and Burma:

Mr. RICHARD SCHENK, 20|1, Lall Bazar Street, CALCUTTA, or to Messrs. T. M. THAKORE & Co., 24, Churchgate Street, BOMBAY.

Chemische Fabrik auf Actien (Vorm. E. SCHERING), Berlin N. 39.

Manufacturers of: **Atophan, Insulin, Arthigon, Urotropin, Cylotropin, Krysolgan, Etc.**

A NEW DISCOVERY

The Serotherapeutic Treatment of

ANAEMIA and HEMORRHAGE

by

HEMOSTYL

of

Dr. ROUSSEL (Paris).

The active element is the **serum** and the **blood** taken entirely from horses prepared by preliminary bleeding in a state of active hematopoiesis.

The **ampoules** contain 10 c.c. of pure **hemopoietic serum** to be injected with a little water in cases of anæmia, and to be injected pure in case of hemorrhage.

The syrup contains nothing but hemopoietic blood in a syrupy medium most agreeable and very soluble and is to be used for anæmia, chlorosis, etc.

The treatment with **HEMOSTYL is the only physiological treatment** of anæmia and is far more efficacious than the old methods with iron, hemoglobin, etc., etc.

Prescribed by 90,000 doctors in England, France, Spain, Italy, Belgium, Central and South America, etc., etc.

In April, 1925, there were at the "Institut de Serotherapie Hemopoietique of Romainville, Paris," 800 horses used for the production of serum.

average. The highest mortality rates in urban areas were 3.83 and 2.28 in Golaghat and Nazira, respectively. There is no segregation hospital in either of these districts and notification is not enforced.

Fevers.—The death rate from fevers showed a decrease from 16.7 per mille of the decennial average to 14.3 for 1925. During the year certain anti-malarial measures were carried out.

At Lumding operations were carried out on the same lines as in previous years. The general condition of some of the important breeding places was improved. The river Haru-Langfer is reported to be the only really serious breeding ground of carrier anopheline species, as *A. listoni* and *A. culicifacies* were found there on several occasions. All breeding places were treated with a mixture of crude oil and castor oil. Cinchona was used with good results. One thousand six hundred and eighty cases of malaria were treated during the year as compared with 2,419 in 1924.

At Haflong a gang of men is employed to remove all undergrowth on edges of drains and sprinkle kerosine oil where there is any collection of water. Their duty is also to cut down all rank vegetation within the station. The edges of lakes were kept free from overhanging grasses and weeds and covered with a film of kerosine oil, to prevent mosquitoes breeding there. The district Civil Surgeon supervises the work of the staff once a month.

The Doom-Dooma Tea Company in Lakhimpur district carried out with good results an anti-malarial work in their gardens under skilled supervision. Other estates in that district are also considering the question of initiating anti-malarial schemes.

During the year anti-malarial measures comprising the following items of work at a cost of Rs. 4,050 were carried out in Kohima town:—(1) cutting of all jungle in the station within a certain radius; (2) daily oiling of all streams; (3) opening up of all sluggish water channels; and (4) bunding up of all seepage collections of water and oiling of the surfaces so obtained. The scheme was commenced on the 15th April, 1925. A staff of 2 sardars and 30 local coolies was engaged and housed in three huts so as to be near the scene of their work. The station was in the course of seven months completely cleared from within ¾ mile of its western cart road and to the foot of the eminence of Kohima Naga village hill. It is at this end of the station that the jungle clearing could not be thorough on account of the vested rights of the Nagas of Kohima village whose land is contiguous and had to be left untouched, though two platoons of the Assam Rifles located here suffered more than the other ranks of the battalion from malaria, viz., Platoons 9 and 10. Cutting down of as much scrub as was permitted in that direction with other prophylactic measures taken undoubtedly helped in controlling the disease. With the exception of the barracks of Platoons 9 and 10, where specimens of *A. maculipennis* were found, most of the flying insects caught were either *Culex* or other gnats. Collections of larvæ from rice fields and pools were hatched out but all proved to be of the culicine variety. During the year only one of the European officers of the Assam Rifles suffered from malaria of benign tertian type. His residence is situated low down on an easterly spur that overhangs a low valley. Special attention was paid to the clearing of the jungle in its vicinity and the officer escaped further attacks of fever.

Kala-azar.—The number of deaths from kala-azar recorded during the year was 6,365 as compared with 5,585 in the preceding year. The recorded deaths from kala-azar in the districts of Sylhet, Goalpara, and Garo Hills were higher than those of the preceding year. The heavy increase from 69 to 535 deaths in the Garo Hills is due to the extension of the registration to the hill *mauzas* during this year, indicating that the disease is more prevalent in the hills than in the plains part of this district. The number of kala-azar patients treated during the year rose from 48,770 in 1924 to 60,940 in 1925. The percentage of deaths to the total treated was 10.44. If the 60,940 patients had remained untreated, 90 per cent. of them or 54,846 persons would have died and inflated the death rate. The provincial organisation for the treatment of kala-azar remained almost the same as in the previous year. As in the previous year, 6 special assistant surgeons and 110 sub-assistant surgeons, the number of the latter being raised from 81 in 1924, were on kala-azar duty, and as usual all sub-assistant surgeons—whether in charge of special kala-azar dispensaries, State or Local Board dispensaries—visited and re-visited villages within a radius of 5 miles of their dispensaries in search of fresh cases, and all cases detected were brought under treatment.

The number of "stopped treatment" cases is showing a tendency to decline, partly on account of the reduction in the length of the course of treatment resulting from the introduction of urea-stibamine, and to magic lantern demonstrations in which the danger or stopping treatment before complete cure is effected is fully explained. 'Stopped treatment" cases are still very high. A partially treated kala-azar patient continues to be infectious to others and it is the duty of all educated people to induce such patients to undergo a complete course of treatment for the good of the community. A pamphlet written in simple language and in a conversational style in which it is laid down that treatment should be continued until cure is effected is being read in primary schools and is being distributed to the general public. Publicity in this manner should show good results. Since the close of the year a pictorial poster displaying the figures of a patient before and after treatment has been printed and is being exhibited in all public places.

As in previous years all sub-assistant surgeons surveyed kala-azar infected villages within a radius of 5 miles of their respective dispensaries, and for the areas not so covered special sub-assistant surgeons were placed on survey duty. As previously the treatment of outdoor patients was carried out by means of sodium antimony tartrate supplied by Burroughs, Wellcome & Co. Since August 1925 in all special kala-azar hospitals and hospitals at the district and sub-divisional headquarters, all kala-azar patients are being treated with an organic compound of antimony called urea-stibamine. The use of urea-stibamine was further extended later in the year to 10 per cent. of outdoor patients attending at the indoor hospitals. The greatest advantage of urea-stibamine over sodium antimony tartrate is that it shortens the course of treatment from about three months to about one month. The price of the former drug is at present too high to allow of its employment generally. Further extension of the use of this drug in so far as this is possible with the money available is under consideration. All assistant surgeons and sub-assistant surgeons ordered to administer urea-stibamine were trained in the technique of administration of the drug at the Pasteur Institute, Shillong.

In the Cachar district no newly infected villages were discovered during the year. The Moibang indoor hospital for kala-azar patients worked satisfactorily. In Sylhet 4 paying wards have been added to the kala-azar hospital at Habiganj, raising the total indoor accommodation to 34 beds. A special ward of 12 beds has been provided in the Sadar Hospital. The hospital at Shatiajuri was closed. There are in the Sylhet district 38 special kala-azar dispensaries with 61 sub-centres, in addition to the usual Local Board dispensaries and 3 dispensaries with 6 sub-centres run by the Kala-azar Relief Association.

In the Goalpara district three new centres for treatment were opened and one was closed. Two Forest Department dispensaries have been equipped for the purpose of treating kala-azar patients during the year. On survey, Khetri *mauza* in the Kamrup district was found to be heavily infected. A survey of the Borpeta sub-division shows that the infection in it is milder than in the Gauhati sub-division. New foci of infection in Tapachamti village in Barkhetri *mauza*, Bidhia in Korua *mauza* and Kamarkuchi village in Upper Shorbhog *mauza* have been detected, and arrangements for treatment in these areas have been made. In Darrang there

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is one kala-azar ward at Tezpur and seven outdoor dispensaries for treatment of kala-azar patients. In the Nowgong district proposals for the establishment of three new treatment centres have been sanctioned during the year. The railway hospital at Lumding continued to treat both railway employees and outsiders. A survey of the whole of the Sibsagar district with the exception of the Mikir Hills was carried out during the year and 75 villages in the Sibsagar sub-division, 56 in the Jorhat sub-division and 117 in the Golaghat sub-division have been found to be lightly infected. The Mikir Hills will be surveyed as soon as a Naga or a Khasi sub-assistant surgeon is available for the work. In the Lakhimpur district a sub-assistant surgeon has been surveying the villages in the North Lakhimpur sub-division. A total of 69 fresh cases were brought under treatment in the Lakhimpur district. All cases appear to be sporadic and no heavy infection has been discovered in any part of this district. In the Garo Hills a proposal to extend the hospital at Tura is under consideration. Owing to the scarcity of Garo sub-assistant surgeons, outdoor treatment in this district gives no promise of success and the only alternative is to enlarge the indoor hospital at Tura and insist on cases from the district being brought into Tura for treatment. It is hoped that the shorter treatment with urea-stibamine will attract Garos to the hospital.

In the Sadiya Frontier Tract, of the nine patients treated, eight were imported from other districts and one who is a native of the district was infected in the Nowgong district. In the Naga Hills district four cases were detected in Dimapur and all of them have been brought under treatment.

The kala-azar section of the report is concluded with the statement, "the very valuable and most interesting researches of the Kala-azar Commission have brought to light the fact that the sandfly (*P. argentipes*) plays an important part in the propagation of kala-azar." (This statement is a somewhat premature one as, up to the present, it has not beeen fully proved that the sandfly, *Phlebotomus argentipes*, is connected with the propagation of kala-azar. Further, it was not the work of the Kala-azar Commission that first brought this sandfly under suspicion.)

Major T. D. Murison, I.M.S., held the post of the Director of Public Health, Assam, during the year; he was however absent on leave from April 5th until December 4th; during this period Major J. B. Hanafin, C.I.E., I.M.S., officiated.

L. E. N.

ANNUAL REPORT OF THE DIRECTOR OF PUBLIC HEALTH, MADRAS, FOR THE YEAR 1925. BY MAJOR A. J. H. RUSSELL, C.B.E., M.A., M.D., D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, MADRAS. MADRAS: SUPERINTENDENT, GOVT. PRINTING. PRICE RE. 1-2-0.

THE year under review must be regarded as almost as unhealthy as the year 1924, owing to the continued high mortality from cholera. The total number of deaths (1,000,558) from all causes, though slightly less than in 1924 (1,006,043), was still much higher than the average for the quinquennium (920,312). Details in regard to the more important diseases are given below.

Cholera.—The disease was practically confined to the southern and south-western districts of the Presidency and was severe in the districts of Madura, Tanjore, Rāmnād, Tinnevelly and South Arcot. Of the northern districts, Anantapur and Gōdāvari East were entirely free from the disease, while in none of the other districts did the mortality exceed 120. The total number of deaths was 44,815 against 51,971 in 1924 and represents a death-rate of 1.1 per mille as compared with 1.3 in 1924 and 0.7 the quinquennial average. The epidemic which prevailed in the cold weather of 1924 continued into 1925 and caused nearly 18,000 deaths during the first quarter of that year. During the second and third quarters, the disease was chiefly confined to those areas where there was an extreme scarcity of water owing to the failure of both the monsoons in 1924 and of the south-west monsoon in 1925. With the advent of the north-east monsoon, cholera rapidly subsided in the non-deltaic dry tracts and broke out in severe form in the deltaic tracts of the southern districts.

The statistical investigations carried out by the Director of Public Health have disclosed the fact that cholera epidemics tend to be most virulent every seventh year and as the disease was at its worst in 1918 when nearly 123,000 deaths were reported, it was anticipated that the incidence of cholera would again be high during 1925. The knowledge resulting from the Director's investigations, however, enabled the public health staff in the districts to be on the alert and to adopt preventive measures in advance, with the result that the of 1925 resulted in considerably fewer deaths than that of 1918.

Since the introduction of the districts health scheme outbreaks of the disease in pilgrim or fair centres have been the exception.

Prophylactic inoculation was carried out on an extensive scale in the Coimbatore and Salem districts. Out of 4,448 persons inoculated only one contracted the disease.

The Government trust that with the aid of grants sanctioned by them for the improvement of the water-supply in rural areas, local bodies will be able to provide a pure water-supply in festival and fair centres, and in villages lying on the main routes leading to them.

Small-pox.—The mortality rose from 18,810 to 20,478. The death-rate was 0.5 per mille of the population against 0.4 in 1924, and a corresponding quinquennial rate. More than half of the total mortality occurred in seven districts (South Arcot, Gōdāvari East, Salem, North Arcot, Guntur, Gōdāvari West and Anantapur). Fifty-six municipalities registered 2,442 deaths from this disease compared with 1,456 in 67 towns in 1924. The largest number of deaths was recorded in Rajahmundry (437), Vizagapatam (205) and Palacole (171). About 74 per cent. of the total mortality occurred among children under ten years of age, showing that the child population of the Presidency is still inadequately protected and that a still more vigorous policy is called for on the part of the local bodies in conducting both primary vaccinations and re-vaccinations. It is reported that in many districts the local bodies do not maintain either an adequate or efficient vaccination staff.

The Government have already commended to local bodies for their adoption a revised scale of pay recommended by the Director for vaccinators and are considering the question of ensuring the employment by local bodies of a qualified and efficient staff. Collectors of districts have been requested to issue instructions to village officers to give immediate information to the health staff of outbreaks of the disease as the spread of infection can only be checked if the first attacks are promptly reported.

Plague.—The number of deaths from plague (2,014) was the lowest on record, since the disease first made its appearance in the Presidency, and represents a death-rate of 0.1 per 1,000, as compared with an equal rate in 1924, and 0.3 the quinquennial average. Nearly 93 per cent. of the total mortality was reported from the districts of Salem (898), Coimbatore (392), Madura (207), Bellary (205), and Rāmnād (176). The municipalities most affected were Salem (699), Pollāchi (141), Calicut (54), Madura (36), Mangalore (33), Periyakulam (22) and Dhārāpuram (21). The benefit of inoculation was amply demonstrated by the fact that in a village in Bellary district where plague broke out, 61 attacks and 15 deaths occurred among 269 uninoculated persons as compared with only 15 attacks and no death among 1,531 inoculated persons.

Malaria.—The incidence from this disease is difficult to ascertain owing to defective registration. The disease was prevalent in almost all the districts of the Presidency and severe epidemics are reported to have occurred in the districts of Anantapur, Bellary and Salem. The rate of incidence in Madras City also increased. The local bodies however do not appear to have taken any

THE discovery of the new synthetic remedy for the treatment of Cystitis, Pyelitis, and other infections of the urinary tract

'CAPROKOL'

(Hexyl-Resorcinol)

marks a new epoch in the treatment of all bacterial infections of the kidneys, bladder and the urinary tract. 'Caprokol' is non-toxic, stable administrable by the mouth, and has forty-five times the bactericidal power of phenol.

It is excreted unchanged by the kidneys in sufficient proportion to impart active bactericidal properties to the urine.

'Caprokol' is supplied in flexible gelatine capsules, each containing 0.15 gram 'Caprokol' in olive oil solution, and in 4-oz. bottles containing a 2½ per cent. solution of 'Caprokol' in olive oil.

'CAPROKOL' (Hexyl-Resorcinol)

is manufactured under **sole** British Licence from the Patentees, Messrs. Sharp & Dohme, Inc., Baltimore.

Drying and Hardening of The Bowel Contents

obviously makes their passage and evacuation more difficult, and thus accounts for their retention and delayed elimination. Schmidt, however, claims that prolonged fæcal retention is the logical cause of this drying and hardening process. To break the "vicious circle" thus created, it is necessary, therefore, not only to soften the fæces and make them plastic, but also to facilitate and hasten their passage. That

AGAROL

is fitted to accomplish the foregoing more satisfactorily than any other remedy can be seen from its unique combination of pure mineral oil, agar-agar and phenolphthalein.

Administered in suitable dosage, Agarol lubricates the canal, and mixing thoroughly with the fæces, makes them soft and plastic, and increases their bulk. As a consequence, the bowel contents are easily passed along and evacuated without distress, straining, or injury to the sensitive tissues of the rectum.

Unlike ordinary laxatives, Agarol is not temporary in its effects, for it restores the natural stimulus to peristalsis, and thus after a reasonable time may be confidently expected to train the bowels so that they will continue to act naturally and produce regular evacuation without the aid of drugs.

Points to Remember—

Agarol is the original mineral oil—agar-agar emulsion, and has these special advantages:

It is perfectly stable, odourless and palatable. It causes no griping, nausea, or any disturbance of digestion or nutrition. It mixes freely with the bowel content; it lubricates without leakage of oil.

No limits of age, season or condition restrict the use of Agarol with safety. It contains no sugar, saccharine, alkalies, alcohol or hypophosphites.

measures to eradicate the disease from the areas under their jurisdiction. The Government trust that they will realize the importance of taking action in this direction and of distributing quinine free of cost to those residing in malarial tracts through the medical officers in-charge of the regular and village dispensaries or other agency. The question of undertaking the free distribution of quinine in *specially* malarial tracts at the cost of Provincial funds is engaging the attention of the Government.

Relapsing Fever was prevalent in a mild form in the districts of Coimbatore, the Nilgiris, South Arcot, Trichinopoly and Kurnool. The special campaign against the disease in the Nilgiris was continued during the year under review and the number of deaths was only 200 compared with 1,368 during 1924. It is reported that the infection was freshly imported through Kanarese coolies from the Mysore State. It is hoped that now that a Health Officer for the district has been permanently sanctioned, a recurrence of this disease in its previous virulent form will be prevented. It is satisfactory that the people in the affected areas have on the whole learnt the value of the preventive measures and of the treatment, though it is reported that some of the higher castes raised strenuous opposition to the steps taken to arrest the spread of the disease.

Respiratory diseases.—The number of deaths from these diseases was 74,591 against 45,180 in 1921 and 64,782 in 1924 or 1.8 per mille of the population against 1.1 and 1.6 per mille in 1921 and 1924 respectively. The progressive increase in the number of deaths recorded under this head is attributed partly to an improvement in registration.

Hookworm.—The investigations so far carried out have shown that the disease is more or less uniformly prevalent throughout the Presidency except in exceptionally dry districts such as Bellary and Anantapur, and that it can be eradicated only if a permanent improvement is effected in rural sanitation by the provision of suitable latrines and their habitual use by the people as a whole. The Local and Municipal and Public Health Advisory Committees which were consulted in the matter, after taking into consideration the great difficulties likely to be experienced in introducing a system involving a revolution in habits which have persisted for centuries, recommended that the scheme to induce the people to use sanitary latrines should be confined at first to one or two villages, the cost of the latrines and sweepers being met by the District Board concerned. The Madura District Board has agreed to try the experiment in a few villages in that district, and has allotted the funds necessary for the purpose.

Registration of vital statistics.—In 1923 the Director of Public Health made certain proposals for the transfer of the work of registration of vital statistics from village officers to Union Boards. It was found however that the proposals could not be given effect to except by an extension of the provisions of the District Municipalities Act to the Unions on the application of the Local Boards concerned, and after consulting District and Union Boards it was seen that the majority were not in favour of the transfer. The proposal was therefore dropped during the year under review. The Director of Public Health has since reported that the Union Boards, in places where they have been entrusted with the work, do not attend to the work satisfactorily.

Since the formation of the district health staff registration of vital statistics has shown a marked improvement in rural areas; that still greater improvement is possible and necessary is shown by the fact that during 1925 the District Health Staff throughout the Presidency detected 74,128 unregistered births, thereby making possible the vaccination of a large number of infants who would otherwise have remained unprotected. There has not been a similar improvement in municipal areas, but with the increase in the number of Municipal Health Officers the registration of vital statistics in these areas should show a definite improvement.

The Director recommended during the course of the year that the form of the monthly returns received from Collectors should be amplified so as to enable deaths from typhoid fever, relapsing fever, kala-azar, influenza, etc., to be shown separately instead of being grouped under the common head "Fevers." His proposals were approved so far as municipal areas were concerned but the Government were unable to accept the suggestion in the case of rural areas as they were of opinion that the village headmen who are the sole agency for registration in this Presidency could not be relied upon to distinguished between these various kinds of disease.

Birth-rate.—There was a slight decrease in the recorded birth-rate of the Presidency from 34.9 to 33.7 per mille, all districts contributing to the decrease except Kurnool, North Arcot, Tanjore Gōdāvari East and the Agency, where an increased number of births was recorded. The birth-rate for the year was, however, higher than that for 1923 (33.1) and the average for the quinquennium 1919—23 (28.8). Except in the Madras City and the Nilgiris where the death-rate was highest, the birth-rate exceeded the death-rate in every district. The registered birth-rate in rural towns rose from 34.0 to 35.0 per mille, while that in municipal towns fell from 37.5 to 37.1. The lowest birth-rates in municipalities were again recorded in Tiruvālur (17.2) and Nandyāl (17.8) as in 1924. Other towns which returned low birth-rates are Tadpatri, Erode, Saidapet, Palacole, Ellore, Cuddapah, Srinangam, Karur, Chicucole, Proddatur and Vizianagram. The low birth-rates in these towns seem to show that registration is defective.

Death-rate.—The recorded death-rate for the Presidency fell from 24.5 to 24.4 per mille. There was a decrease in fifteen districts. The largest decrease occurred in the Nilgiri and Bellary districts, due in the former case to the successful campaign carried on against relapsing fever which had prevailed in the district in a virulent form during 1924, and in the case of Bellary to the absence of epidemics of cholera and plague and an improvement in economic conditions. The increase in the death-rate was most marked in the Madras City, the Agency Tracts and in the districts of Rāmnād and Vizagapatam. The recorded death-rate for rural towns and municipal areas rose from 24.1 to 24.8 and from 32.2 to 32.3 per mille respectively. The infantile death-rate during the year was 180.9 per mille of registered births against 179.2 in 1924, the slight increase being due to the smaller number of births registered during the year.

Maternity and Child Welfare.—The total number of deaths registered from causes associated with child birth was 3,788 or 2.7 per 1,000 births against 2,601 or 1.8 per 1,000 births in 1924. This figure does not, however, probably represent the actual mortality. The information obtained by the Director of Public Health from the 22 municipalities where health officers were employed, shows that 43,477 births and 747 maternal deaths were registered in these municipal towns during the year, giving a maternal death-rate of 17.5 per 1,000 births. This high death-rate cannot be regarded as surprising, in view of the fact that in only 6 per cent of the registered labour cases did women receive skilled attention during confinement. These facts show that extensive measures for maternity relief are urgently required, if the maternal death-rate is to be appreciably reduced. The number of Maternity Relief and Child Welfare centres was only 58 at the end of 1925, while the number of trained midwives who worked in the Presidency was only 840.

It is clear that the number of centres and midwives must be largely increased if any real improvement is to be effected. The Government have recently sanctioned a scheme for the training of "dhais" at District Headquarter Hospitals and they trust that local bodies will take full advantage of this scheme so that even in the remoter areas of the Presidency skilled attention may be made available to women during labour.

Propaganda.—Considerable attention was devoted to health propaganda during the year. As many as 52,100 lectures were delivered during the course of the year at 36,800 centres to audiences numbering approximately 2,900,000. The largest amount of propaganda work was carried out during the National Health and Baby Week. It is satisfactory that the local bodies and the public in general took an active interest in the matter and made

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the movement a success. The Director's suggestion that local bodies should make contributions to the Madras Health Council to enable it to meet its increasing expenditure is commended to the local bodies for their consideration. The Director reports that with a few notable exceptions (Cuddapah for example) no health propaganda work was carried on in those municipal towns where no health officers were employed. The Government hope that the municipal councils in these towns will realize the great value of propaganda work in the prevention of disease and will devote greater attention to this important matter.

Sanitary works.—No new water-supply or drainage scheme was brought into operation during the year. The schemes to provide a piped water-supply for Chingleput, Bellary, and Coimbatore, the construction of a service reservoir for the Negapatam water-works, and the drainage schemes for Madura and Vellore were under execution, besides several schemes for the improvement of existing water-supply systems, of which the most important were schemes to improve the supply to Coonoor, Vellore, and Salem.

The question of reorganizing the Sanitary Engineering Department so as to enable it to carry out the investigation of water-supply and drainage schemes more promptly is under the consideration of the Government. The Sanitary Engineer has also recommended that his Department should be entrusted with the execution of the schemes for which it prepares plans and estimates.

Administration.—The employment of eleven addition municipal health officers was sanctioned during the year, four of the first class and seven of the second class. At the end of the year therefore, the public health staff under the Director consisted of 3 Assistant Directors of Public Health, 55 Health Officers and 261 Health Inspectors as compared with 1 Assistant Director of Public Health, 5 Health Officers and 189 Health Inspectors in 1920.

In the concluding sections of his very able report, Major Russell has some very interesting comments to make on the general aspects of public health policy in India in general and in the Madras Presidency in particular:—

"It must be remembered that India has now taken its place as an important member of the international organizations of the world. This country is, moreover, not only the home of cholera, but is a constant potential source of infection as regards plague, small-pox and other epidemic diseases. It is, therefore, necessary to abandon the merely parochial outlook on public health questions, and to remember that the nations of the world look to India itself to do what it can, and much more than it has done in the past, to eradicate these dangerous diseases. The League of Nations Health Section has focussed the attention of the educated world on public health, to a degree which has never before been reached, and other nations will judge India and its peoples by the capacity which its internal health organizations exhibit in controlling those diseases which are a constant source of danger to the world at large.

"The first and foremost problem awaiting consideration, and probably the key to most other public health schemes in India, is rural sanitation. The International Health Board of the Rockefeller Foundation has during the last six years carried out anti-hookworm work in certain selected districts of the Presidency, and has, in addition to general surveys, conducted intensive educational campaigns in the same areas. The Government has provided annual allotments for this work, but there is a danger that the policy of the International Health Board will be lost sight of. So far as this Presidency is concerned, the hookworm campaign has not resulted in any *permanent* improvement, because there has been no practical response to the repeated warnings as regards the danger of soil pollution and the necessity for the construction and proper use of suitable private and public latrines. This is not wholly the fault of local bodies, but whatever the cause, the time has now come for making a move, and it is suggested that from now onwards Government should sanction yearly grants for this purpose. In several instances district and *taluk* boards have already sanctioned varying amounts in their annual budgets for rural conservancy, so that the need for such expenditure is being recognized. Two district boards have set aside very considerable sums for this work during 1926-27, and simultaneously with the construction of latrines, the Ankylostomiasis Bureau will carry on an intensive educational campaign, so that the scheme may be given every chance of success. Only in this way will something practical towards a general scheme of rural sanitation be carried through, and, if the present experiment proves successful, the International Health Board will be encouraged to continue its work in the Presidency instead of withdrawing altogether. It may be said that the scheme deals only with a very primitive health measure, but one must start with primitive measures amongst a population whose knowledge of Public Health is primitive.'

"Another important and much-needed reform is the framing of a Public Health Act for the Presidency which will not only embody all public health laws and regulations now scattered through a large number of minor statutes, but will put these in a form more suitable for present requirements. Government have called for detailed proposals and these will be submitted shortly.

"It is probably correct to say that nothing in the Presidency is more urgently required than safe and adequate rural water-supplies. Only then can diseases like cholera, dysentery and enteric fever be tackled in earnest. During recent years, the Public Health Department has devoted considerable time to the investigation of foci of infection as regards water-borne diseases, and the information now available would be of immense use, if Government and local bodies could set apart year by year, definite sums for the improvement and protection of water-supplies at these foci and along the known routes of spread of infection. The provision of good drinking water at such centres as Palni and Tadpatri Municipalities ought to be dealt with from the Presidency point of view, and the schemes liberally subsidized from Government funds, if, indeed, Government do not bear the whole cost. Moreover, all expenditure on rural water-supplies, specially when supplemented with Government grants such as have been made during the year, should be so arranged that the most urgent works, from the point of view of water-borne diseases, are taken up first.

"Another activity of the Public Health Department which demands immediate extension is the education of the people in hygiene. We have reached a stage in the evolution of public health where an enlightened public opinion is necessary in order to carry it further. If general education is an affair of the State, so much the more is education in matters of public health, for appreciation by the people of the value of public health measures is the surest way to gain the financial support necessary to carry out modern sanitary measures. For the last three years, the Madras Health Council has struggled with a meagre income (aided by the Red Cross Society) to do what it could in this direction. During 1925-26, Government sanctioned a grant of Rs. 13,000 to the Health Council. Of this total, only Rs. 8,000 is a recurring grant and Rs. 3,000 is earmarked for the National Health and Baby Week. How far this sum will go towards financing any adequate health education campaign for a population comprising nearly 43 millions of people and using at least half a dozen different languages can best be imagined. Unless the Health Council can find other sources of income, it may be necessary for that body to suspend its activities. In such an event, it would be essential for Government to sanction the establishment of a health propaganda section under the charge of a suitably qualified officer in the office of the Director of Public Health. The importance and value of health propaganda work has been so definitely established, that it would be impossible to ignore the demands for its continuation in one form or another.

Averting Relapse

It frequently happens in critical stages of illness that a rapid restorative is needed in order to support a patient during a period of physical exhaustion. In such crises, the well-known restorative and stimulant powers of Bovril are of great value. Bovril is the concentrated essence of beef, containing its strengthening and its nutritive properties in a form immediately assimilable and rapidly effective.

In chronic constipation, intestinal stasis, mucous colitis

Petrolagar

(trade mark)

THE outstanding success of Petrolagar is a tribute to its clinical efficiency.

This unique product has grown to a dominant position because of the success attended by its use in the treatment of constipation.

When you prescribe Petrolagar you may be assured of satisfactory results.

Petrolagar is a fine palatable emulsion of paraffin oil and agar-agar which will produce a soft, easily-moved mass in the intestinal tract.

To acquaint you with Petrolagar, our representatives in India will be glad to send you interesting literature on request.

"As an indication of the expansion of the Public Health Department during the past five years, the following figures may be of interest:—

	1920	1926
Assistant Directors of Public Health	1	3
Health Officers	5 (Not Provincial)	55
Health Inspectors ..	109 + 80 (Cholera parties)	261

"Most local boards allot small grants in their annual budgets for rural sanitation, but this money is not always spent to the best advantage. It has been suggested in a circular issued to all District Health Officers that they should select one or more villages in suitable parts of their districts, and persuade the local boards to utilize the sanctioned grants in carrying out sanitary improvements in these villages. In other words, an attempt should be made to have a few "model" villages in each district. District Health Officers and Health Inspectors should make frequent inspections and should encourage the visits of local board members. All expenditure should be closely supervised and village committees might raise sufficient enthusiasm to ensure the observance of sanitary rules. These villages, if suitably selected, should serve as a practical illustration of the advantages of a hygienic environment to a large proportion of the population, and thus help to create a demand for better conditions in other villages and towns, whilst some return for the expenditure made would be apparent."

Correspondence.

MEDICAL EDUCATION AND REGISTRATION IN INDIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—During a stay of four years in Europe, I have been especially interested in the subject of medical education and registration in European countries, have attended various conferences in Berlin and Paris dealing with the subject, and interviewed the President and Chairman of the Educational Board of the General Medical Council of Great Britain. In India matters in this connection are in such a backward state that they call for reform. One would suggest that such measures as the following are urgently needed:—

(1) The establishment of a central Council of Medical Education and Registration for all-India, to be composed of members representative of the different provincial Medical Councils, the different medical colleges and schools in India, and of the medical profession in the country in general.

(2) The appointment of an official Inspector of medical examinations, colleges and schools in India—an appointment to be made by the India Office in collaboration with the General Medical Council of Great Britain. I understand that, as far as the medical examination of those Indian universities whose degrees are recognised by the General Medical Council of Great Britain are recognised, this step has already been taken, but perhaps wider powers and more extensive inspection are needed. Inspection should also take place of the courses of study and examination held by the different women's medical schools in India.

(3) The drawing up of an Indian Pharmacopœia, published under the direction of the proposed all-India Council of Medical Education and Registration. A Pharmacological Society for India should be established with various local centres for teaching and examining. Systematic research is also called for in connection with the indigenous systems of medicine in India under the direction of some such body.

(4) A liaison officer should also be appointed to visit the various centres of medical teaching and examination in Europe, England and America, and to make reports on the methods there current to the Council in India.

(5) One—or possibly two—representatives from India should be appointed to the General Medical Council of the United Kingdom. One European and one Indian representative would be the best.

(6) There is urgent need for the establishment of a Dental School for India, of the passing of an Indian Dental Registration Act, and the setting up of an Indian Dental Board.

(7) The rules with regard to medical registration in the various colonies of the Empire require to be studied, and some uniformity introduced with regard to mutual recognition and registration *vis-à-vis* India.

(8) Legislation is needed in India with regard to the appointment and powers of coroners, the registration of births and deaths, the registration of nursing homes, and with regard to dangerous drugs.

(9) The preliminary scientific examinations leading up to a medical career should be held three times a year, and the courses for them should be made more elastic; thus logic should be made one of the optional subjects, and French and German should be introduced as secondary languages.

(10) There is urgent need for the extension of voluntary hospitals in India; also for the closer association of the independent medical profession in the country with State-aided hospitals, and for the training of a class of ward-assistants who will not be qualified medical men, but who should be available for city as well as for *mofussil* hospitals and dispensaries.

(11) The progress of medicine in India would be greatly assisted by the formation of an Indian Medical Association on the lines of the British Medical Association, the American Medical Association, and the medical associations of other countries.

Among various minor reforms called for are that every medical college and school in India should issue a printed syllabus shewing exactly the character and details of the various courses of study pursued, and the names of its tutorial staff. Many such institutions already do so, but others do not. Study tours for students might also be instituted, for travelling in itself is an education, and exchanging of ideas one of the best methods of learning. An all-India medical students' conference also suggests itself.

There is no doubt that if a comprehensive survey were made of the conditions of medical education and registration in India, very important reforms could be instituted, with great benefit to the country.—Yours, etc.,

K. M. HIRANANDANI.
Sub-Assistant Surgeon.

HYDERABAD, SIND,
15th September, 1926.

A CASE OF ACUTE GLOSSITIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The publication on p. 448 of your issue for September 1926 by Dr. Gopal Singh Chawla of a case of acute glossitis reminds me of a similar case seen by me in this district in April 1925. Details of the case are as follows:—

The patient, a Hindu male, aged about 50 years, was brought to this dispensary on the evening of the 1st April 1925 in a cart. He was partly unconscious and had to be carried to the ward. He was restless and with a flushed face; the tongue was purple in colour, hugely swollen, and protruding for more than an inch outside the mouth, with a constant dribble of saliva from the angles of the mouth. His temperature was 104°F., pulse fairly good, respirations quickened and impeded; the heart and lungs appear to be normal, the liver and spleen not enlarged, but the abdomen a little distended.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

His relatives stated that when taking his evening meal on the previous night he had suddenly complained of pain at the base of the tongue. Next morning fever ensued and the swelling of the tongue commenced. As they objected to my using a knife, I had recourse to the hypodermic syringe and injected 6 m. of tincture of iodine in 2 c.c. of distilled water intravenously. A dose of calomel gr. iv. with sodium bicarbonate was introduced into the mouth with difficulty, and an enema given.

That night he had a severe reactionary temperature and profuse sweating, but next morning the temperature was only 99.8°F. and the tongue considerably reduced in size. He could not speak, but made signs. On examination of the tongue superficial ulcers covered with thin whitish yellow sloughs were seen situated on the upper and left lateral part of the posterior third of the tongue, close to some sharp-edged and dirty molar teeth. Permanganate and alum mouth washes were now prescribed, and Mist. Salina with potassium iodide. The temperature dropped to normal by 4 p.m., but the patient was still unable to speak. By the 5th April he had made a complete recovery and spoke normally.

Having no microscope in my dispensary, I was unable to incriminate any causative organism, and had to content myself with a diagnosis of acute ulcerative glossitis.—Yours, etc.,

S. K. BHAVE,

Medical Officer, Hirekerur, Dharwar District, Bombay Presidency.

21st October, 1926.

A FATAL CASE OF INFECTION WITH *ASCARIS LUMBRICOIDES*.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Dr. Nauhorya's notes in your issue for August 1926 on a case of acute intestinal obstruction caused by *Ascaris lumbricoides* remind me of a typical case seen by me some ten years ago, when a medical student of the Berry-White Medical School, Dibrugarh.

The patient, an adult Hindu male, was admitted to hospital with all the clinical signs and symptoms of acute intestinal obstruction, but the presence of roundworms was not for a moment suspected. He was operated upon by Dr. H. K. Das, L.M.S., then Teacher of Surgery at the School, and now Civil Surgeon of Nowgong, Assam. At operation about 500 roundworms were removed, and when placed in a bowl presented a truly remarkable sight. In spite of all precautions taken the patient unfortunately died on the table before the operation was completed.—Yours, etc.,

M. BAROOA, L.M.P.

MANCOTTA TEA ESTATE,
DIBRUGARH P. O., ASSAM,
15th October, 1926.

A CASE FOR DIAGNOSIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the note on p. 526 of your issue for October 1926, under this heading, may I suggest that it was the injection of atropine on a hot day in the Punjab that caused the rise of temperature described?

Some years ago a patient with acute rheumatic fever was given an injection of morphine and atropine by the family physician, and at 10 p.m. suddenly developed a temperature of 107°F., about half an hour after the injection. The temperature at the time of injection was only 101°F. This case occurred in May 1921, and the patient was dead before any doctor could be called in.—Yours, etc.,

INTRAMUSCULAR QUININE IN MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have seen the correspondence on this subject in two or more numbers of the *Gazette*, and perhaps I may be permitted to record my experience in it. Some years ago I was in charge of a hospital in a malarious district, and, if my memory serves me right, I had occasion to treat about 740 cases microscopically proved to be malaria in 2 years and 10 months' time. I administered over 3,000 intramuscular injections of quinine during this period and a few intravenous injections also. I met with no unpleasant results whatever. I might say that I had only 3 abscess formations in the whole series. I fail therefore to appreciate the fears expressed by your correspondents, and in my opinion, if due care be taken, quinine can be administered intramuscularly without any untoward consequences.—Yours, etc.,

PNEUMOPERITONEUM IN RADIOGRAPHY.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In your review of my book "A descriptive Atlas of Visceral Radiograms" in your issue for September 1926, p. 470, you note the omission from it of the method of inducing pneumoperitoneum in radiography of the viscera. I am not a radiologist, but see a good deal of *x*-ray work, and have only actually seen one pneumoperitoneum. I understand that the method is accompanied by more danger than its results would warrant. I may add that it is rarely done in this country.

I should be grateful if you would make a note of this in your columns.—Yours, etc.,

A. P. BERTWISTLE, M.B., CH.B., F.R.C.S. (Ed.).

OBITUARY.

THE LATE DR. H. M. CRAKE.

IT is with the deepest regret that we have learnt of the recent death at Home of Dr. H. M. Crake, Health Officer to the Calcutta Corporation. "Like many other medical men, Dr. Crake knew that he was engaged in a war with conditions that he could not hope to see swept away in his lifetime" remarks the *Statesman*. "Religious and social forms were all the time fighting against his desire to bring light into the dark places of the city. His epitaph must be that he wore himself out in public service, content that at the end of the day a little progress should have been made."

Dr. Crake came out to India first as one of the special officers appointed by the Secretary of State in 1898-1899 on the first outbreak of plague in Calcutta, his services being retained in that capacity until 1906, when he was appointed a District Health Officer. His work in connection with the sanitary survey of Burra Bazar and other congested areas of Calcutta City prepared data of very great value for the new thoroughfares and town-planning activities of the Calcutta Improvement Trust. In 1913 he was appointed Health Officer to the Calcutta Corporation and was re-appointed to the same post in 1923, and again in 1926. Much of his energy in Calcutta was devoted to the establishment and extension of maternity and prenatal welfare centres and schemes, and the infantile mortality in Calcutta was always the subject of his closest attention. In conjunction with the Calcutta School of Tropical Medicine he took vigorous steps to deal with kala-azar in the city, whilst the terrible incidence of tuberculosis and its special association with

the *purdah* system were subjects to which he frequently drew attention.

Dr. Crake was one who believed in co-operation. His presence at the monthly staff conferences at the Calcutta School of Tropical Medicine was always very welcome, and his advice and information at such conferences invaluable. We have reviewed many of his annual reports in our columns, and there were no reports of greater interest; from first to last he visualised and grasped the conditions present in this great and crowded city, planned well and wisely for their amelioration, and strove for reform. In Dr. Crake Calcutta has lost one of her foremost and most energetic of pioneers.

"I first came in contact with Dr. Crake," writes a contributor (A. D. S.), "in connection with the yearly Health Exhibitions held during Baby Week. Afterwards we had many mutual consultations on various matters of public health interest. I was very early impressed by Dr. Crake's openness of character, his honesty of purpose and his generous nature; by his lively appreciation of any advances in medical knowledge and his quick adaptation of these to the need of the city under his care. His views on health matters were broad and he was in no way parochial in his outlook; any request for advice and help or co-operation was met at once with ready and immediate response.

"Dr. Crake's organisation for dealing with the annual passage of many thousands of pilgrims through Calcutta was not only of benefit to the people of Calcutta, but to Bengal also, and indeed to the whole of India. His knowledge, experience, and temperament made him an ideal colleague, and not only Calcutta but the province of Bengal has lost a valuable worker and well wisher."

Service Notes.

APPOINTMENTS AND TRANSFERS.

Brevet-Colonel R. A. Needham, C.I.E., D.S.O., M.D., I.M.S., is placed on special duty under the Director-General, Indian Medical Service, as Inspector of Medical Education on behalf of the General Medical Council of the United Kingdom with effect from the 22nd October 1926.

Lieutenant-Colonel J. C. H. Leicester, M.D., F.R.C.P., F.R.C.S., V.H.S., I.M.S., is appointed to officiate as Surgeon-General with the Government of Bengal, with effect from the 2nd November 1926 and until further orders.

Lieutenant-Colonel H. Innes, M.D., I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals and Prisons, Assam, with effect from the 1st November 1926 and until further orders.

Lieutenant-Colonel R. F. Baird, I.M.S., is appointed to officiate as Inspector-General of Civil Hospitals, United Provinces, with effect from the 9th October 1926 and until further orders.

Lieutenant-Colonel G. Tate, M.B., V.H.S., I.M.S., Professor of Midwifery, King Edward Medical College, Lahore, is appointed to be Inspector-General of Civil Hospitals, United Provinces, with effect from the 9th November 1926.

The undermentioned officers are appointed substantively to the Medical Research Department with effect from the dates mentioned against their names:—

Captain A. C. Craighead, M.B., I.M.S. 1st July 1926.

Lieutenant-Colonel R. McCarrison, C.I.E., M.D., I.M.S. 29th July 1926.

Major V. B. Green-Armytage, M.D., I.M.S., Second Professor of Midwifery and Gynæcology, Medical College, Calcutta, is appointed to act as Professor of Midwifery, Medical College, Calcutta, and Obstetric Physician and Surgeon, Medical College Hospitals, with effect from the afternoon of the 1st November 1926, vice Lieutenant-Colonel J. C. H. Leicester, V.H.S., I.M.S.

Major E. W. O'G. Kirwan, M.B., F.R.C.S.I., I.M.S., officiating Professor of Ophthalmic Surgery, Medical College, Calcutta, and Ophthalmic Surgeon, College Hospital, is appointed to act as Civil Surgeon, Mymensingh, with effect from the date on which he joins the appointment.

Major W. P. Hogg, D.S.O., I.M.S., is appointed to officiate as an Agency Surgeon, and is posted as Civil Surgeon, Quetta, with effect from the 9th October 1926.

On return from the Andaman and Nicobar Islands, Major G. Covell, M.D., I.M.S., resumed charge of his appointment as officiating Assistant Director, Central Research Institute, Kasauli, with effect from the forenoon of the 29th September 1926.

Major P. C. Banerji, I.M.S., Resident Surgeon, Medical College Hospitals, Calcutta, is appointed to act, in addition to his own duties, as Resident Physician of that institution, with effect from the afternoon of the 7th May 1926 until further orders.

Major R. F. D. MacGregor, M.C., I.M.S., an officiating Agency Surgeon, is appointed to officiate as Residency Surgeon, Indore, with effect from the 28th September 1926 and until further orders.

Major A. N. Dickson, M.C., I.M.S., Agency Surgeon, Bundelkhand, is appointed to officiate as Administrative Medical Officer in Central India, in addition to his own duties, with effect from the 28th September 1926 and until further orders.

The services of Captain J. C. Chukerbutti, M.B., I.M.S., are placed temporarily at the disposal of the Government of Bengal, with effect from the date on which he assumes charge of his duties.

Captain Mahdo Prasad, M.B., I.M.S., was restored to the Active List with effect from the "16th February 1925" and not from the "6th March 1925" as notified in the London Gazette dated 1st May 1926.

Subject to His Majesty's approval, the undermentioned officer has been appointed permanetly to the Indian Medical Service, as Lieutenant by the Right Hon'ble the Secretary of State for India. His Commission will bear date 31st March 1925.

Thomas Arthur Doran, M.B.

The undermentioned gentlemen to be temporary Lieutenants, subject to His Majesty's approval:—

Dhirendra Nath Basu, M.B. Dated 5th September 1926.

Hardit Singh Ahluwalia, M.B., B.S. Dated 8th September 1926.

Bonbehari Bhattacharji, M.B. Dated 9th September 1926.

Frederick Placidus Lisboa-Pinto. Dated 10th October 1926.

Benegal Mukunda Rao, M.B., B.S. Dated 6th November 1926.

Nasiruddin Ahmed, M.B., B.S. Dated 18th October 1926.

LEAVE.

Colonel A. W. R. Cochrane, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for 5 months and 27 days combined with leave on half average pay for 1 year, 10 months and 3 days, with effect from the 9th October 1926.

Lieutenant-Colonel W. R. Battye, D.S.O., I.M.S., an Agency Surgeon, is granted leave on average pay for 1 month and on half average pay for 5 months under Fundamental Rules, with effect from the 28th September 1926.

In modification of this Department Notification No. 1397, dated the 13th October 1926, Colonel C. H. Bensley, C.I.E., K.H.P., I.M.S., Inspector-General, Civil Hospitals and Prisons, Assam, is granted 4 months leave on average pay, preparatory to retirement, with effect from the 1st November 1926 or any subsequent date on which he may avail himself of it.

Lieutenant-Colonel F. E. Wilson, I.M.S., an Agency Surgeon, is granted leave on average pay for six months under the Fundamental Rules with effect from the 9th October 1926.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

George Browse, D.S.O., M.D., vice Colonel Edgar Francis Eardley Bains, D.S.O., retired. Dated 10th October 1926.

Captain (now Major) A. MacD. Dick, O.B.E., F.R.C.S., I.M.S., is granted the acting rank of Major from 4th January 1918 to 1st October 1918 and from 14th October 1918 to 8th October 1920 and is granted the acting rank of Lieutenant-Colonel from 2nd to 13th October 1918, whilst serving with the Mesopotamian Expeditionary Force.

Lieutenant to be Captain.

Thomas Arthur Doran, M.B. Dated 23rd May 1925.

Temporary Lieutenants to be temporary Captains.

Subbier Annaswami. Dated 3rd October 1926.
Sarveshwar Nath Kaul. Dated 4th October 1926.
Hari Narain Shivapuri. Dated 5th October 1926.
Amar Nath Duggal. Dated 12th October 1926.
Homi Meherjibhoy Setna. Dated 14th October 1926.
Bankim Kumar Pal. Dated 15th October 1926.
Chandranan Joshi. Dated 20th October 1926.
Bakhtyar Rustomji Hakim. Dated 29th October 1926.
Kongattil Madhava Menon. Dated 31st October 1926.

RESIGNATIONS.

Lieutenant Ragade Sanjiva Rao. Dated 31st October 1926.

Lieutenant Ponathil Balakrishna Kurup. Dated 1st November 1926.

RETIREMENT.

The King has approved the retirement of Colonel E. F. E. Baines, D.S.O., I.M.S., with effect from the 10th October 1926.

MISCELLANEOUS.

Subject to His Majesty's approval, the date when mobilized service began, the date of appointment and the date of rank of the undermentioned officers are as noted below. They will take their seniority in the service accordingly:—

NAME.	Date when mobilized service began.	Date of appointment.	Date of rank.
Captain R. W. H. Miller, M.B.	10-4-1920*	28-1-1925	10-4-1923
Captain G. J. Smith, M.B.	7-4-1921*	3-3-1925	7-4-1924
Lieut. S. P. Joshi, M.B.	25-5-1923	20-5-1925	25-5-1923
,, T. J. Davidson, M.B.	6-6-1923*	22-12-1923	6-6-1923
Lieut. S. D. Gupta, M.B.	7-8-1923	20-5-1925	7-8-1923
,, E. G. Michelson, M.B.	9-9-1923*	29-11-1923	9-9-1923
Lieut. K. M. Bharucha, M.B.	13-10-1923	20-5-1925	13-10-1923
Lieut. D. MacD. Fraser, M.B.	25-2-1924*	28-1-1925	25-2-1924
Lieut. S. C. H. Worseldine	14-4-1924*	3-3-1925	14-4-1924
Lieut. M. K. Afridi, M.B.	1-8-1924	20-5-1925	1-8-1924
Lieut. G. S. Chawla, M.D.	9-8-1924	20-5-1925	9-8-1924

NOTES.

MESSRS. NEWTON AND WRIGHT'S PRICE LIST OF ELECTRO-MEDICAL APPARATUS.

WE have received from Messrs. Newton and Wright, 471|3, Hornsey Road, London, N. 19, a copy of their very interesting illustrated price list of electro-medical apparatus. This deals with faradic batteries, galvanic batteries, combined batteries, switchboards, sinusoidal apparatus, their Omnistat universal machine, electrodes and accessories for electro-medical applications, the Bergonie apparatus, electric cauteries, mechanical vibrators for massage, and heat and light baths. The catalogue will be of interest to medical men working in this line; whilst other catalogues dealing with apparatus for ultra-violet therapy, diathermy, and *x*-ray work can be obtained post free upon request.

CLEAN AIR.

A NEW apparatus which has aroused considerable interest of late in the London newspapers, and which will interest the medical profession in India is the "Andrew air filter," manufactured by Air Filters, Ltd., Fitzalan House, Arundel Street, London, W.C. 2. The principle of this apparatus, which is electrically driven, is to suck in contaminated air through a perforated cone, pass it through a perforated charcoal container to purify it, then through medicated peat, and finally out again. A demonstration was given at a boxing match in Blackfriars Road, London,—one of the most slummy areas of London—on September 13th, 1926. Ordinarily the atmosphere in this room is such that one can hardly see through it for tobacco smoke and dust. Five air filters were fitted, and according to the London newspapers "the air was as pure as one could hope to find on Dartmoor."

It is claimed for these air filters that they will cleanse any stuffy or tainted atmosphere, sterilize a sick room after epidemic disease, circulate 360 cubic feet of air per minute on a very low electric current consumption, clear fog, smoke, and all taint of tobacco from closed rooms, and exterminate flying insects such as mosquitoes. It is obvious that the special use in India for such an apparatus will be in cinemas, theatres, and lecture halls, but it may also be of great value in operating theatres, surgical wards, nursing homes, etc. The apparatus is claimed to be fool-proof, with a self-lubricating motor, and thoroughly insulated, whilst it is of a convenient size and weight for easy transfer from room to room. The Indian agent is H. Rolfe, P. O. Box 186, Calcutta.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c|o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to the *Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of the *Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

A NEW CONCEPTION OF THE EPIDEMIOLOGY AND ENDEMIOLOGY OF CHOLERA.*

By J. W. TOMB, O.B.E., M.D., D.P.H.,

Chief Sanitary Officer, Asansol Mines Board of Health

and

G. C. MAITRA,

CAPT., I.M.S.,

Research Worker, School of Tropical Medicine and Hygiene, Calcutta.

(*Mining Association, Endowment.*)

CHOLERA was attributed by Koch in the year 1883 to the presence in the human intestine of a "comma-bacillus" or vibrio possessing certain morphological and cultural characteristics. As man alone amongst animals is subject to cholera, it is impossible to satisfy Koch's own postulates regarding the causal relationship of this vibrio to the disease. Nevertheless, the "comma-bacillus" or vibrio of Koch is generally accepted as the causal organisim of cholera. In addition to the morphological and cultural characteristics of the vibrio as originally described by Koch, later observers added the serological characteristic of "specific agglutinability" and claimed that vibrios not possessing this agglutinability were not "true" cholera vibrios, though in every other respect indistinguishable from the vibrio described by Koch.

Further investigations revealed the fact that sporadic cholera—a disease indistinguishable clinically from epidemic cholera—is very constantly associated with non-agglutinating vibrios which differ from the vibrio of Koch in "agglutinability" alone.

Extended search by many observers in many parts of the world also proved that no chronic carriers of agglutinating vibrios could be demonstrated; nevertheless, it was inferred on the analogy of carriers of the *Bacillus typhosus* that such carriers of agglutinating vibrios must exist and that the disease lay dormant in these carriers in the intervals between epidemic outbreaks, in spite of the fact that all attempts to demonstrate such carriers had proved negative. Spontaneous outbreaks of epidemic cholera had also been observed to occur in many places where no history of immediate infection from any outside source could be obtained or be reasonably inferred.

It was also frequently assumed that Bengal was the only endemic home of cholera and that every outbreak of cholera in every other country of the world could theoretically be ultimately traced to its origin in Bengal. Our researches however into cholera in the endemic area of the Asansol Mining Settlement, Bengal, have led us to a new conception of the epidemiology as well as the endemiology of this disease.

In the first place, it was observed by us that during the dry hot weather in the Asansol Mining Settlement (March to June) vibrios were very numerous in the ponds or ground tanks much frequented by the inhabitants of the Settlement for washing after defæcation. On washing being prohibited in these tanks under the *Regulations for the Prevention and Control of Cholera in the Asansol Mining Settlement,* it was found that vibrios gradually diminished in number and always disappeared after 12 to 14 days. We, therefore, concluded that the vibrios found by us in these tanks were derived from pollution of the water with human fæces, but when we attempted to isolate vibrios from the stools of those frequenting the tanks our efforts were a complete failure. As there could be no doubt, however, that the source of the vibrios in the tanks was the human intestine, we concluded that the ordinary peptone enrichment process for isolating vibrios from solid stools was unsatisfactory. We therefore set out to discover a method modelled on Nature and after much experiment by trial and error devised what we shall refer to as the "open-bowl" method of cultivating vibrios from stools, which was fully described in the *Indian Medical Gazette* of February 1926, p. 56 and November 1926, p. 537. The method briefly is as follows:—

Enamelled bowls of 500 c.c. capacity are used, each containing 250 c.c. of 1 per cent. salt solution together with a few c.c. of 1 per cent. peptone solution.

Each whole stool is first thoroughly emulsified in 400 c.c. of 1 per cent. saline solution and allowed to settle for 6 hours in a conical glass; 40 to 50 c.c. of the clear supernatant fluid being then inseminated into one of the enamelled bowls.

For the examination of stools of cholera cases and also as a rule of cholera contacts, a different method is used. Small quantities of the cholera stools to be examined are first inseminated by means of dry pieces of wood or twigs from a neighbouring tree into large test tubes (6 in. × 1 in.) containing 10 to 15 c.c. of 1 per cent. salt solution. To the salt solution in those test tubes we have found that the addition of peptone is unnecessary, since 1 per cent. salt solution is a selective medium in which vibrios temporarily multiply whilst other fæcal organisms are either held in check or die out.

On the arrival of the test tubes in the laboratory, or after 2 to 6 hours at room temperature, about six large loopfuls of the surface liquid in the tubes are inseminated into the bowls described above.

The inoculated bowls in both cases are left in lockers at room temperature, protected from dust and air, a few loopfuls of the surface layer of the

Digitized by Arya Samaj Foundation Chennai and eGangotri

bowls being tested daily for the presence or absence of vibrios by intensive methods of cultivation through peptone medium and subsequent plating out on bile-salt agar. Should vibrios not appear in the bowls within one week they are considered negative. In positive cases, vibrios as a rule, appear within two to three days, and when abundant, persist in the bowls up to four weeks.

By means of the "open-bowl" method we have been able to prove that in many localities of the endemic area of the Mining Settlement as many as 35 per cent. of the inhabitants are chronic carriers of non-agglutinating vibrios.

With regard to clinical cholera we early ascertained as mentioned above that two bacteriological types existed—sporadic cholera and epidemic cholera. Sporadic cholera we found in every respect identical with epidemic cholera, save only in its apparently non-infectious or feebly infectious character and in the fact that it is associated with "non-agglutinating" vibrios. Mackie and Storer(1) however have recorded an outbreak of clinical cholera in a military hospital in Alexandria, which was due to non-agglutinating vibrios. They also cite the case of a human volunteer who developed severe symptoms of clinical cholera after experimental ingestion of non-agglutinating vibrios, and our experimental rabbits after intravenous injection of these vibrios invariably suffered from severe diarrhœa and toxæmia. Epidemic cholera on the other hand is highly infectious and is constantly associated with "agglutinating" vibrios—sometimes however of varying degrees of "agglutinability." It is obvious therefore that "agglutinability" in a vibrio is not essential for the causation of the symptom-complex known as cholera, though the communicability of the disease would seem to be closely associated with this characteristic.

In our efforts to demonstrate the identity of agglutinating and non-agglutinating vibrios found in cases of clinical cholera, we first attempted to convert the non-agglutinating into the agglutinating form by animal experiments.

With this object in view we injected a non-agglutinating vibrio intravenously into a rabbit and on the unexpected death of the rabbit after six days we recovered a partially agglutinating vibrio from its gall-bladder, which was found to be capable of absorbing about 80 per cent. of the agglutinin from high titre Koch's serum.

In another instance we made a vaccine of a non-agglutinating vibrio obtained from a case of sporadic cholera and injected it intravenously into a human volunteer having no agglutinin in his blood for Koch's vibrio. The serum of this volunteer was then found to be able partially to agglutinate Koch's vibrio (1:20).

Our efforts to convert the non-agglutinating into the agglutinating form, while proving that the two vibrios are closely allied serologically, were however inconclusive and inconstant in results. We therefore decided to abandon this idea and to attempt the conversion of the agglutinating into the non-agglutinating form instead.

For this purpose a fresh cholera stool which was subsequently proved in the laboratory to contain great numbers of agglutinating vibrios was inseminated into a ground tank, the water of which had also been proved to be free of vibrios. Samples of the water of the tank in the vicinity of the inseminated stool were then tested every two hours and it was found that the agglutinating vibrios in the cholera stool permanently changed *en masse* into the non-agglutinating form under natural conditions in the ground tank after 12 to 14 hours. This experiment we repeated several times with the same result. Laboratory cultures of Koch's vibrios were also similarly tested and were found to change into the non-agglutinating form after 24 to 36 hours. Agglutinability is therefore mainly an artificial property developed and fixed by laboratory cultivation, since laboratory cultures of agglutinating vibrios take approximately three times as long as the vibrios in the stools from which they are derived to lose their agglutinability under natural conditions in ground tanks.

Extended examinations of the stools of epidemic cholera convalescents showed that 80 per cent. of these convalescents became chronic carriers of non-agglutinating vibrios, the agglutinating form permanently disappearing from the within two to four weeks.

An identical loss of "specific" agglutinability in the Shiga-Flexner group of *B. dysenteriæ* in the intestines of survivors of bacillary dysentery has recently been described by Calalb(2). Analogous serological variations are also recorded by Greig in a "water" vibrio(3); by Cunningham in the spirochæte of relapsing fever(4); by Uhlenhuth and Grossman in the leptospiræ of Weil's disease(5) and by workers in South Africa in the *Bacillus pestis* of plague(6). Five per cent. of healthy contact carriers of agglutinating vibrios, likewise become chronic carriers of non-agglutinating vibrios, the remainder freeing themselves altogether of vibrionic infestation within two four weeks.

Furthermore, it has been a matter of common observation in many countries where cholera occurs in epidemic form, that during epidemics (due to agglutinating vibrios) non-agglutinating vibrios invariably appear in great numbers in contaminated water supplies (sewers, etc.), the non-agglutinating vibrios disappearing *pari passu* with the disappearance of the epidemic.

Vibrios of varying degrees of agglutinability have also been found by us in eleven cases of epidemic cholera, and in two cases we have isolated both non-agglutinating and agglutinating vibrios from the same cholera stool.

In the laboratories of the Department of Public Health in Egypt vibrios agglutinating with standard serum only below 1:1000 are not considered "true" cholera vibrios.

After examination of thousands of stools we have been unable to discover one permanent carrier of agglutinating vibrios in the Mining

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Settlement and no such carrier has ever been reported by any other observers elsewhere.

We have therefore been driven to the unavoidable conclusion that the non-agglutinating vibrio (which is itself capable of causing clinical cholera) takes on the agglutinating characteristic under certain bio-chemico-physical conditions in the human intestine the nature of which are at present unknown, and in this mutation or epidemic form is the cause of epidemic cholera, since it is not unreasonable to assume that a characteristic so unstable may as easily be acquired as lost.

Non-agglutinating intestinal vibrios therefore in our opinion constitute the reservoir of cholera both epidemic and endemic, the degree of non-agglutinability in a vibrio apparently depending not only on the nature of its surroundings but also on the period of time which has elapsed since it last existed in agglutinating or epidemic form. The nearer to the threshold of agglutinability a non-agglutinating vibrio is, the more closely would it seem to be allied both serologically and epidemiologically to the agglutinating vibrio.

During the cold weather in the Mining Settlement (November to February) vibrios are so scarce as to be practically non-existent in the water of ground tanks commonly used by the inhabitants for the double purpose of bathing and drinking, but with the onset of the hot weather (March) they begin to make their appearance and become very numerous as the hot weather advances. It was observed by us that during the hot weather thunder-showers always considerably increased the numbers of vibrios demonstrable in the tanks. In this connection it is of interest to note that small showers during the hot dry weather are popularly credited in those parts of Bengal where cholera is epidemic at that season of the year with the capacity of increasing the intensity of existing cholera epidemics. Chemical analyses of surface washings after these thunder-showers showed that the percentage of salts as well as of organic matter in them is very high. This would reasonably account for the exacerbation of existing epidemics owing to the rapid multiplication of vibrios in infested tanks following the increase of their saline and organic contents. With the establishment of the monsoon, vibrios decrease greatly in numbers and are even found temporarily to disappear when rain falls continuously for one or more days. During breaks in the monsoon, however, vibrios are always to be found in considerable numbers in ground tanks.

The curve of cholera in the Asansol Mining Settlement was found by us very closely to follow the curve of the vibrionic contents of surface water supplies (ground tanks), the annual epidemic season being confined to the hot weather (March to May) when vibrios are very numerous, with occasional epidemic outbreaks throughout the rains when vibrios are often present in considerable numbers, followed by a period of almost complete quiescence during the cold dry season when vibrios are extremely scanty or non-existent. It is to be noted that the annual rise and fall of the number of vibrios in ground tanks, although closely related to the epidemic curve of cholera, is entirely independent of the actual *existence* of cholera in epidemic form and occurs whether cholera exists or not.

The endemicity of cholera in any locality in our opinion depends primarily upon the existence in the community of great numbers of (healthy) carriers of non-agglutinating vibrios; secondly, on the occasional conversion in the intestines of a proportion of these carriers—by some vital process—of the non-agglutinating vibrio into its mutation form the agglutinating vibrio; thirdly, upon the widespread and continued pollution of drinking water supplies (generally surface water supplies, i.e., ground tanks) with this mutation form through the unhygienic habits and customs of the people; and fourthly, upon the capacity of vibrios to persist or multiply in the drinking water supplies of the locality owing to climatic conditions, a vicious cycle being thus established.

When once therefore cholera has been introduced into a community in widespread epidemic form, great numbers of chronic carriers of non-agglutinating vibrios remain—apparently for years—amongst whom cholera of the sporadic or the epidemic type may occur at any time, and if owing to the unhygienic habits and customs of the people drinking water supplies are habitually contaminated by them, then cholera will become endemic in such a locality, provided that the climatic conditions are suitable for the survival and multiplication of vibrios in the drinking water supplies.

On the contrary where wholesale pollution of drinking water supplies does not occur, or where conditions are unfavourable to the persistence or multiplication of vibrios in the drinking water supplies, cholera cannot become endemic. In these circumstances also epidemic outbreaks, if such occur, cannot become widespread or sustained in character and will "fizzle out," as they are reported by Col. Gill ordinarily to do in the Punjab during the hot dry weather.(7) Cholera, therefore, in our opinion can only become epidemic in any locality during those periods of the year when owing to climatic conditions vibrios are capable of persisting or multiplying in the drinking water supplies of that locality.

We also venture to predict that in the deltaic area of Bengal, vibrios will be found to persist or multiply in the surface water supplies of that area at the two periods of the year only when cholera is ordinarily epidemic there, one during the hot dry weather immediately before the annual inundation of the country and the other immediately after the inundation has subsided while temperature is still high and before the onset of the cold weather, the flooding of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

country during the rains as well as the fall in temperature during the cold weather being both unfavourable to the growth or persistence of vibrios in the surface water supplies there.

On the other hand, in the dry and arid regions of North-Western India, the epidemic season of cholera is in general confined to the rains, since only during that season is there the necessary amount of surface water, as well as the necessary temperature (associated with the insanitary habits of the people) to make an epidemic of cholera possible.

Where the percentage of chronic carriers of non-agglutinating vibrios remains small, spontaneous outbreaks of cholera will be infrequent, and in such areas cholera if it occurs at all will be chiefly an imported disease.

We have been unable to ascertain by experiment whether or not the agglutinating vibrio immediately after it has lost agglutinability is still capable of conveying epidemic cholera, but from our combined observations in the field and laboratory we conclude that the vibrio is capable of conveying cholera for some time after agglutinability has been lost, and a probable instance of this kind has been recorded by Chalmers and Westerfield as having occurred in Gindha.* An additional factor, therefore, in the spread of epidemic cholera is the period of time which has elapsed between the contamination of drinking water with the agglutinating vibrio and its ingestion as a non-agglutinating vibrio by non-immunes.

RADIUM AND THE CURE OF CANCER.†

By J. A. SHORTEN, B.A., M.B., B.Ch., M.R.C.P. (Lond.), MAJOR, I.M.S.

THE position of radium in the treatment of cancer is a question of absorbing interest, not only to the medical profession, but to the community at large. No method of treatment has ever been so beset with alternating hope and despair. No method has been so extolled by some and so damned by others. What are the causes of this lack of uniformity in result and wide divergence of opinion? During my recent visit to Europe, I was afforded the opportunity of examining some twenty "follow-up" cases of uterine cancer at St. Bartholmew's Hospital, and had the privilege of a visit to the Curie Fondation in Paris. I feel, therefore, that my views on the above subject may be of interest to the medical profession in India.

The announcement of the discovery of radium was made at the Académie de Sciences in Paris on the 26th December, 1898—about 28 years ago—in a joint paper by M. and Mme. Curie.

The first to discover the action of radium on human tissues was the late Henri Becquerel, who, having carried about in his pocket a small packet of radium, contracted and suffered for some months from a chronic ulcer of the adjacent skin.

This observation was duly confirmed by Pierre Curie, who deliberately produced the same result after an application of ten hours. It was then that M. Curie set himself to work to turn this apparently evil force to good account. Some radium was presented to a doctor of the St. Louis Hospital, and he used it with great care and moderate success in the treatment of certain skin diseases.

This was the beginning of radium therapy. Space prevents me from tracing further the development of this treatment up to the present day. The alternating hopes and disappointments are only too well-known to you all.

Before entering on the main subject of my paper, I will describe to you some personal experiences of treatment with radium. For some months I have had the use of a quantity of radium salt equivalent to 60 milligrammes of radium element. This is contained in 3 tubes of approximately 20 milligrammes each. With this I have treated some half dozen cases of cancer of the cervix uteri, a few cases of cancer of the pharynx, tongue and cheek, with varying success.

My first experience with radium however was in a case of rapidly growing carcinoma of the larynx. This patient in the absence of radium was treated first of all by *x*-rays. A standard Coolidge tube, backing up a 9-inch spark gap, was used. The rays were filtered through 5 millimetres of aluminum. He received in all about 680 milliampere-minutes at a skin distance of 9 inches in a month. The result was nothing short of dramatic. The ulcer in the larynx almost healed. A large secondary gland in the neck melted away as if by magic, and the patient returned to work. Then the radium arrived and in the course of 23 days he received to the interior of the larynx 600 radium element hours (screen: ½ mm. platinum and 1 mm. of rubber), and externally to either side 1,750 radium element hours through 4 mm. of lead. The result of this treatment (which was endorsed by the only authority on radium in India at the time) was intense necrosis of the mucous membrane of the larynx, with exfoliation of some of the cartileges.

Tracheotomy was performed on the 30th May, and the patient died on the 11th June, three months after he had come under treatment.

I have dealt with this case in some detail, because it represents the usual history of such cases, viz., preliminary success, with final disaster.

Of the other cases of which I have notes, the following are the details:—

Carcinoma of the Cervix—five cases.

Case 1.—An advanced case with extension into the broad ligament and base of the bladder. There was continuous hæmorrhage for some months. She had in all 3,120 mgm. hours of radium element. The immediate effect was encouraging. Hæmorrhage entirely ceased. She returned 3 months later with marked cachexia, and considerable pain on vaginal examination, due to adhesive vaginitis. She died a month later.

Case 2.—An inoperable case, with continuous bleeding for 9 months, and a fungating growth of the cervix. She had 5,880 mgm. hours. Three months after treatment there was so sign of existing disease. At the end of 5 months the patient was still well.

Case 3.—This case was also an advanced one of carcinoma of the cervix uteri. There was a hard nodular mass occupying both lips of the cervix, and adherent to the vaginal wall on the left side. The opening of the cervical canal could not be located. This patient first received 60 mgms. radium element in 3 tubes screened 1 mm. silver and 1 mm. rubber, disposed around the cervix for 24 hours. After 10 days another 12 hours' exposure with the same amount of radium was given, and finally after 30 days it was possible to introduce 40 mgms. of radium element into the cervical canal, the total exposure being 3,280 mgm. hours. Seven weeks after the first exposure there was remarkable improvement. Ulceration had disappeared and the mass as felt per rectum was much smaller and softer. There was a moderate degree of adhesive vaginitis.

Cases 4 and 5.—Cases with extensive involvement of the vaginal wall. Treatment was undertaken for the alleviation of symptoms—hæmorrhage and pain. Both were much improved when last seen, about one month after treatment.

Sarcoma of the Cervix—one case.

This was a case of inoperable sarcoma of the cervix in a young woman of 30, referred to me by the Eden Hospital authorities, after histological examination. She received internally 2,640 mgm. hours radium element with the usual screening, and externally 2,160 mgm. hours. The growth disappeared completely, and she was discharged cured after about 2 months.

The technique followed in the above cases was as follows:—

Three tubes containing 60 mgms. radium element, with a total screening of 1 mm. silver and 1 mm. of rubber, were placed in the vagina and around the cervix for 24 hours; 2 tubes (40 mgms. radium element) were introduced into the cervix and uterine cavity for 24 hours, and 3 tubes (60 mgms. radium element), screened 1 mm. of silver, at a distance of 1 cm. from the skin were placed in the right and left iliac fossæ and in the midline above the pubis, for 12 hours in each place. The latter part of the treatment I now omit for reasons I will explain later.

Cancer of the Mouth, Tongue, and Larynx—seven cases, including one case of myeloid sarcoma of the upper jaw which had previously been successfully operated on.

The technique adopted in these cases was—

Three tubes, containing 20 mgms. radium element each, at 8 cm. from the skin externally for 12 hours; and about 40 to 60 mgms. radium element screened 1 mm. silver and 1 mm. rubber internally for about 6 hours. All these cases improved, temporarily at any rate, and the results were encouraging except in 2 cases, one of carcinoma of the cheek, which had about 3,000 mgm. hours in all but became steadily worse after temporary improvement, and a case of sarcoma of the neck which had external treatment only with great reduction in the size of the growth externally but extension internally after a month or two with paralysis of the vocal cord on that side.

During my recent visit to England, I saw 20 follow-up cases of carcinoma of the cervix with Dr. Malcolm Donaldson at St. Bartholomew's Hospital. These cases had been treated with 50 mgms. of radium element for 144 hours. The radium was applied in platinum needles ½ mm. thick, introduced into the substance of the growth. The series included 2 cases dating from 1921. In addition to these there were 6 cases apparently cured, including two of 2 and 3 years duration respectively. In two of the cured cases the radium had been introduced intraperitoneally as well as *per vaginam*.

There was one case which had been treated by deep *x*-ray therapy, but had a large recurrent mass in the right iliac fossa.

In all cases bleeding had stopped since the termination of the treatment, and there were only a couple of cases with any vaginal discharge at all. Practically all cases showed evidence of adhesive vaginitis. One patient complained of increased pain.

On the 1st July, 1926, I formed one of a party of 30 physicians and surgeons who paid a visit to the Fondation Curie in Paris. This institution being primarily a research institute, treats only selected cases of cancer of the uterus, tongue, cheek, and pharynx, and recently cancer of the rectum. Their idea is to treat only cases in which the results can be adequately checked.

The principles on which the work is carried out are as follows:—

Cancer of the Cervix Uteri.

1. Only cases in which there is a definite hope of cure are treated. These are practically what the average surgeon would consider operable. No cases are treated for palliation.

2. Histological examination of the growth is first made in all cases, except in sarcoma when sections are made after moderate exposure to prevent the possibility of dissemination.

3. Filtered gamma rays are now used exclusively. All techniques involving the use of alpha and beta rays have been abandoned.

4. The main aim of treatment is to give the dose which will destroy the malignant cells without destroying the normal tissues.

5. When possible, the complete treatment is given at one sitting, to prevent sensitization of healthy cells or increase in the resistance of malignant cells.

6. Treatment of recurrence after radiation gives bad results and therefore is not usually undertaken.

The results obtained in cases of carcinoma of the cervix are shown in the accompanying tables, from which it will be seen that there is a steady improvement in the percentage of cures from 1919 to 1924, especially in the cases classed as operable. This improvement is to a certain extent due to more careful selection of cases, but also to improved methods of application.

Cancer of the Tongue.

In the case of cancer of the tongue the general principles are the same. The routine treatment adopted at present is, firstly, the introduction locally into the growth of platinum needles containing radium. The needles have walls 1 mm. thick; they are placed 1 to 2 cms. apart, and an average of 6 to 10 needles is used for each case. The radium in each needle is distributed in one or more foçi, each containing 1.25 mgms. radium element, and the total dose is expressed in mgm. hours as usual. The needles are allowed to remain *in situ* for varying times depending on the amount of radium employed. The average time would appear to be 6 to 8 days. If we take for example 6 needles containing one focus of 1.25 mgms. of radium element, and allow these to remain *in situ* for 8 days, we shall get a total dose of 1,440 mgm. hours.

If any of the cervical glands are enlarged, a block dissection of the neck is done, removing the sterno-mastoid muscle, jugular vein, and the whole chain of lymphatic glands *en bloc*. The glands are then examined microscopically, and, if malignant cells are found, the whole neck from the lower jaw to the clavicle is radiated with a flat applicator containing 1 to 2 mgms. radium element per square centimetre at a distance of two centimetres from the skin. Very frequently it is found that the enlarged glands are due to septic absorption and do not contain any carcinomatous cells. In such cases surface radiation is dispensed with.

The results obtained are shown in the accompanying Table II. During the two periods shown it will be seen that from 20 to 25 per cent. of cures may be expected. That percentage has since been improved on and now about 34 per cent. of cures is obtained.

TABLE I.

Carcinoma of Cervix.

	Number of cases.	Discharged cured.	Inoperable, cured.		Just operable, cured.	
1919	103	9·1%	69	4·7%	34	21·7%

Attempts are now being made to treat cancer of the cheeks as well as malignant conditions of the face and neighbouring parts, with some success. In this connection a word of warning may be uttered. Cross-fire methods are still in vogue in some clinics, but in Paris it was found, in the case of cancer of the floor of the mouth, when with the intention of producing a cross-fire effect tubes of radium were placed on the floor of the mouth and externally on the skin at the same time, intense necrosis of the floor of the mouth resulted. This is due to the caustic effect of the characteristic rays produced from the metal enclosing the radium. Cross-fire therefore should be consecutive, not simultaneous.

From what has been written above it will be seen that the results of the treatment of cancer by radium are steadily improving. At the Fondation Curie clinic I saw 15 cases of cancer of the tongue, ranging in duration after treatment from 3 to 6 years, apparently cured. The gamma ray of radium has been proved to demonstration when applied in appropriate doses to be capable of destroying carcinomatous cells while it leaves the normal tissue cells comparatively unaffected. It may be asked "Why then can we not cure every case of cancer?" The answer is to be found in the law of inverse squares, which states that in all forms of radiation the intensity at a distance from the source varies inversely as the square of the distance. For instance, in the case of radium, the effect on a cell at a distance of 1 mm. is one thousand times that at a distance of 1 cm. This is a stupendous fact to face, and as inexorable as the law of gravitation. Practically it means this, if we place a tube of radium on the surface of a malignant mass for a time determined by the maximum dose the skin will bear, we shall destroy the malignant tissue up to a certain distance from the tube, while immediately beyond this the malignant cells will be stimulated for a certain distance, and still further away the effect will be nil. Bumm showed in the case of cancer of the cervix on post-mortem examination of cases treated by radium that the malignant cells are destroyed for a distance of 3 cms. only. The net result then is that by application of radium we have actually done more harm than good. Such is the effect of the radium diminution of intensity of radiation in accordance with the law of inverse squares.

Now there are two possible ways by which we may counteract the influence of the law of inverse squares. We can, for instance, aim at producing a uniform radiation throughout the whole mass of malignant tissue. Theoretically this may be done by distributing the radium in needles placed at appropriate distances from one another, so that all malignant cells lying between the needles receive a lethal dose. In practice, however, there are many insuperable difficulties. In the first place only a few tumours are accessible to treatment by this method, and we meet with the same difficulties as the surgeon who attempts to excise the growth, viz., we have no means of determining how far the growth has extended through lymphatic and other channels outside the tumour mass. For this reason we may reasonably assume that this method will never attain complete success, although, just as is the case with surgery, brilliant results may occasionally be obtained.

The second method depends on the fact that radiation such as light proceeding from a point becomes for all practical purposes a parallel beam at a distance of 6 metres. At that distance two points at a distance of 10 cms. would receive approximately the same amount of radiation, and therefore it should be possible to give the calculated lethal dose to all malignant tissue distributed throughout the thickness of the body. In between these limits it can be shown by a simple calculation, that by increasing the distance of the radium from the skin the total dose received at a fixed distance below the skin can be increased.

Thus I find that with 60 mgms. radium emanation I get an erythema of the skin at 1 cm. distance in 12 hours. And therefore if the radium is placed at a distance of 3 cms. from the skin the erythema dose according to the law of inverse squares will be 108 hours.

If we now consider the effect on a malignant cell 3 cms. below the skin, in the first instance we give it a dose of say x units per hour or a total of 12 x. In the second instance we shall give $16|36 = 4|9$ x per hour for 108 hours, which works out as a total dose of 48 x, or exactly 4 times as much. The same effect may of course be produced by quadrupling the amount of radium. The problem would therefore seem to resolve itself into the employment of a sufficient quantity of radium to enable one to use it at a sufficient distance to make the depth dose practically equal to the skin dose. The French have already realised the possibilities underlying this theory. They are now experimenting with an apparatus containing 4 gms. of radium. This is placed at a distance of 10 cms. from the skin, the rays are filtered through 1 mm. of platinum. Exposures vary from 60 to 70 hours. Remarkable results in carcinoma of the cervix, and carcinoma of the rectum are already claimed for this method, but as it is still in the experimental stage they have not been published.

It will be readily recognised that the modern tendency is to use the radium tube in the same way as the *x*-rays tube, and it is possible that if sufficient quantities of radium were available, radium therapy would replace deep *x*-ray therapy altogether. It is unlikely that *x*-ray apparatus capable of producing a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

ray of a wave length comparable to that of the gamma ray of radium will be produced in the near future. On the other hand, at the moment both agents possess certain specific advantages and it seems only reasonable that they should be considered complementary rather than antagonistic in the treatment of disease. For instance, in the treatment of cancer of the cervix uteri, it seems reasonable to conclude that the best form of treatment is the application of radium locally, with deep x-ray therapy to the pelvic glands and lymphatics.

Finally, I may record the opinion that radium is a double-edged sword, and if employed in insufficient quantities by inexperienced persons it is likely to do more harm than good.

SOME OBSERVATIONS ON THE ERUPTION OF TEETH.

By P. S. KHOSLA, M.B., B.S. (Edin.), L.D.S.,

Medical Officer, Mirpur, Kashmir State.

DETERMINATION of age in the living is a question of every day importance to the practitioner medico-legally, and the importance of teeth in its estimation is not inconsiderable. Of the two chief tests, i.e., the time of appearance of certain centres of ossification and the time of eruption of teeth, the latter is of greater service to the practitioner for he cannot always invoke the help of x-rays in determining the centres of ossification. There is no doubt that the time of ossification is a more reliable guide and helps us to determine the age up to 25 years, while teeth are of help only up to the age of 18, yet they are a more convenient guide. Beyond 25 the age determination is a matter of guesswork.

As the teeth are of such importance medico-legally, it may be of interest to record certain freaks of Nature against the general average time of their appearance. During the last year I have come across three such cases:—

Case 1.—I was consulted about a Hindu male child the next day after its birth regarding the pain it caused the mother in suckling. On examination the lower central incisor was seen coming out of gums. There was no history of any venereal disease in the parents.

Case 2.—A Hindu lady aged 32 who was wearing partial upper and lower dentures consulted me about the rest of her teeth. Certain of them were affected with pyorrhœa and were taken out by me. A fortnight after the extractions the patient began to complain of pain in the hind part of her gums. On examination it was found that the wisdom teeth were making their appearance. The gum on the tense spot was lanced. The teeth both in the upper and the lower jaws are now fully erupted and painless.

Case 3.—A Mahommedan male child, aged about 8 years, was brought to me for extraction of an upper front tooth which was situated on the inner side of the arch. The tooth on examination was found to be a misplaced permanent canine. On further careful examination the dentition was found to be peculiar inasmuch as that the upper jaw revealed all the premolars in place, thus indicating the age to be nearly 12 years, while the lower jaw showed all the temporary molars and canines in place, indicating the age to be about 8 years, which was corroborated by the parents and the general appearance of the child. Two plaster models were prepared by me from impressions taken in stent of the child's mouth. The photograph of the models is sent herewith.

THE RESULT OF ARTIFICIAL PNEUMOTHORAX TREATMENT IN PULMONARY TUBERCULOSIS, WITH A SYNOPSIS OF 182 CASES.

By Rao Bahadur M. KESAVA PAI, M.D.,
Director, Tuberculosis Institute and Superintendent, Tuberculosis Hospital, Madras.

THOUGH the Hippocratic School seems to have practised artificial pneumothorax in pleurisy and other pulmonary conditions 2,000 years ago, the first application of this treatment by the modern method was by Forlanini of Pavia in 1894 and Murphy of Chicago in 1898. Pneumothorax therapy is now employed by physicians in most parts of the world with signal success.

The principle on which this treatment is based is the enforced rest given to the diseased lung by introducing air into the pleural cavity and collapsing the organ by equalizing the atmospheric pressure inside and outside the lung. The contraction of the lung tissue not only results in the ejection of the toxic contents of the cavities and the bronchial tubes, but prevents the further accumulation of these products and hastens the process of fibrosis and repair.

Different kinds of apparatus have been used by different workers but Lillingston and Pearson's apparatus which is the simplest and the best was used throughout in my work, the water manometer fitted to the apparatus being the indicator of the introduction of the needle into the pleural cavity. Morphia ($\frac{1}{4}$ gr.) with atropine (1|150 gr.) was injected before the initial operation and novocaine (2 per cent.) with adrenalin was invariably injected into the track of the pneumothorax needle about 3 minutes before puncture. Ordinary sterile, filtered atmospheric air was used for the inflations.

The usual difficulties and complications encountered by pneumothorax therapists all the world over were experienced. The operation failed completely in 15 per cent. of cases on account of continuous adhesions. In 61 per cent. of cases partial pneumothorax alone could be induced and in 24 per cent. a good pneumothorax was produced. The last includes cases where slight adhesions were present which did not prevent the collapse of the lung to a satisfactory extent. Thin bands of adhesions often gave way during the successive refills and rendered the collapse more complete. About 250 c.c. of air was introduced during the initial operation and increasing amounts during successive refills, the maximum quantity given at any time not exceeding 800 c.c. and usually not exceeding 500 c.c. The average Indian chest being smaller than the European, the latter quantity was found by experience to be the average maximum that the Indian chest could take in, whilst 700 to 800 c.c. could usually be put into a European patient. The intervals between the refills were slowly increased from 2 days to 3 weeks.

The usual accidents met with during pneumothorax treatment occurred in the series. Slight pleural shock, dyspnœa, and cardiac embarrassment were occasionally seen but did not interfere with the progress of the case. Pleural effusion resulted in 22 per cent. of cases but was not so large as to necessitate aspiration. Subcutaneous emphysema occurred in a number of cases but was of no consequence. Deep emphysema occurred in one case due to puncture of the lung but produced no serious consequences, the patient getting over the dyspnœa and dysphagia in 3 or 4 days, by the natural closing of the puncture and absorption of the air.

TABLE III.

Comparative results of Artificial Pneumothorax Treatment and of Ordinary Treatment in Stages II and III of Pulmonary Tuberculosis.

	Total cases.	Cases that benefited in Stage II.	Cases that benefited in Stage III.	Cases in which T.B. disappeared from sputum.
Pneumothorax treatment.	93	100 %	82 %	53 %
Ordinary treatment.	344	77·8 %	30·5 %	17·4 %

The results of pneumothorax treatment in the series are given in the above tables. Ordinary medicinal and sanatorium methods were used in addition to the collapse therapy, but a comparison with an analysis of 344 cases treated in the hospital during 3 years without pneumothorax brings out the comparative value of this form of treatment. The series was constituted of cases in the more advanced stages of pulmonary tuberculosis from all parts of India. It will be seen that whereas 22 per cent. of cases were arrested in Stages II and III by pneumothorax treatment, only 14 per cent. of cases obtained the same benefit by ordinary treatment and whilst a total of 100 per cent. and 82 per cent. of cases benefited in Stages II and III respectively by pneumothorax, 77.8 per cent. and 30.5 per cent. only benefited by ordinary treatment: 53 per cent. cases became bacillus negative by pneumothorax treatment, as contrasted with 17.4 per cent. by ordinary treatment.

The progress of the disease was remarkably affected by the successive inflations. High temperatures which had resisted weeks and months of ordinary treatment came down to normal or nearly so in a few days or weeks and the sputum became bacillus negative in a remarkably short time, often in 3 to 5 weeks. The effect produced was indeed dramatic in some cases and the treatment became so widely popular that every patient began to ask for it.

There is usually a slight fall in weight during the preliminary stages of artificial pneumothorax therapy, which has been variously put down to displacement of the mediastinum and pressure on the liver and stomach, but the patients soon regain this lost weight and put on further flesh and strength in the later stages of the treatment.

Pneumothorax therapy is applicable to about 5 per cent. only of all cases. There is no object in applying the treatment to the early cases in Stage I, as ordinary treatment suffices for these, but in such of these early cases in which ordinary treatment fails to do good in about 3 months, artificial pneumothorax should be employed. Unilateral cases, cases with less than one-third of the opposite lung implicated, cases of severe hæmoptysis, pulmonary abscess, bronchiectasis, etc., come under the category of suitable cases, but extensive bilateral involvement, advanced diabetes, cardiac and renal complications and peritonitis and intestinal ulceration contraindicate the employment of pneumothorax therapy. Different workers have employed different standards in the choice of cases, but generally speaking whilst unilateral cases free from pleural adhesions give the best results, bilateral cases even of an advanced type show greater or less improvement, if not actual arrest. In fact whilst an apparent cure results when the opposite lung is comparatively healthy, an amelioration is invariably effected even when there is advanced implication of the less diseased lung. Above all,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

collapse therapy by rendering the sputum bacillus-negative, or reducing the number of bacilli, considerably curtails the chances of spread of infection. The drawback to the treatment is that *x*-ray examination of the cases has to be conducted before and during the course of the inflations. Unless the condition of the collapsed and the healthier lung is closely watched by skiagrams or by fluoroscopy one might be startled by some disastrous results. Deep seated disease in the opposite lung not detected by physical examination might spread and give disappointing results, or a superficial cavity in the lung to be collapsed might get punctured by the pneumothorax needle and produce the disastrous consequences of pulmonary rupture.

One great advantage of the treatment is that it can be conducted in the midst of busy towns and cities with results that compare favourably with those obtained in sanatoria in salubrious climates by the same treatment. The patient will be living all the time under conditions not very different from those of his domestic surroundings and can adapt himself to his home conditions immediately on the cessation of the treatment.

AN APPARENTLY INFECTIOUS OUTBREAK OF THE EPIDEMIC DROPSY FORM OF BERIBERI.

By I. R. ANDERSON, M.B., Ch.B.,
U. F. C. Mission Hospital, Kalna, Bengal.

ON 27th July, 1926, J. M. and his family, suffering from epidemic dropsy, came to live at Kalna where, up to that time, there had not been any signs of the disease. They lived in the house of Mrs. M, at "A" in the map for two days, and then went to live with Mrs. K at "B" in the map. On 2nd August S., a servant of J. M., came to Kalna. He was also suffering from epidemic dropsy and was admitted to hospital. He spent a great deal of his time with B. M. at "C" in the map. Meanwhile, on 1st August, Mrs. M developed the signs and symptoms of epidemic dropsy. On 9th August Mrs. K. also developed epidemic dropsy, and B. M. on 12th August. Thereafter, during the following month, numerous other cases of epidemic dropsy occurred locally, the last case developing on the 7th September.

The outbreak occurred amongst the Mission workers living at Kalna. The Mission hospital is situated about one mile from the centre of the town, and round about it there are living those who work in the hospital, i.e., doctors, compounders and nurses, and also several teachers—both male and female—who teach in the Mission Schools. In addition to these, there are also several menial servants living in the compound.

Imported Cases.—Unfortunately accurate records were not taken of the five "imported cases." There is no doubt, however, that they were all suffering from the disease which was at the time so prevalent in Calcutta and other districts. The infected persons came from Gosaba, in the Sunderbans, where the disease was widespread. The following table illustrates the severity of the disease in each case and the relationship of the cases to one another:—

TABLE I.

Imported Cases.

Case No.	Age.	Sex.	Oedema.	Diarrhœa.	Fever.	Dyspnœa.	Pain on pressure.	Knee reflex.
1	J. M. 35	M	++++	++	+	+++	+++	?
2	J. M.'s wife 34	F	+++	++	+	+++	++	?
3	J. M.'s child 2	F	+++	+	+	++	?	?
4	J. M.'s nephew 5	M	++	—	—	—	—	+
5	S—servant 15	M	++++	++	+	+++	++	—

Some of the details of the signs and symptoms of the disease were as follows:—

(1) *Fever.*—Intermittent low fever, the temperature rising to 99° or 100°. The fever did not yield to quinine. Case No. 5, who was under observation in hospital, had fever for about forty days.

(2) *Oedema.*—A continuous firm œdema of the feet and legs, and a transient œdema of the face and hands, that of the face being marked in the morning.

(3) *Dyspnœa.*—There was marked breathlessness both on exertion and at rest.

(4) *Gastro-Intestinal Symptoms.*—Seven or eight loose motions daily. No vomiting. Loss of appetite.

(5) *Pain.*—Pain in the calves of the legs on pressure was marked. In some cases there was a continuous pain. There was also marked muscular weakness.

(6) *Knee Reflex.*—Examined only in two cases.

(7) *Urine.*—Albumen free.

Local Cases.—In all, eighteen cases of the disease occurred locally. On the whole the disease in these cases was of a slightly milder nature, with the exception of case No. 1 who was acutely ill. The severity of the disease was less in the cases occurring late, the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

disease in the last five cases being of a very mild type. Table II gives details of the signs and symptoms in each case; while Table III shows the relationship of case to case.

TABLE II.

Local Cases.

Case No.	Oedema.	Diarrhœa.	Fever.	Dyspnœa.	Pain on pressure.	Delayed second cardiac sound.	Knee reflex.
1	++++	+++	+	+++	+++	+	++
2	++	+++	+	++	—	+	+
3	+++	+++	—	++	—	—	—
4	++	—	—	++	++	—	+
5	++	—	—	+	—	—	—
6	+++	—	—	+++	—	—	—
7	+++	+++	—	+++	++	+	+
8	+++	—	+	+++	++	+	—
9	++	++	—	+++	++	?	?
10	+++	++	—	+++	++	+	—
11	+++	—	—	+++	+++	+	—
12	+++	—	—	+++	—	—	—
13	+++	++	—	+++	++	+	—
14	++	++	—	+	—	—	—
15	++	—	—	++	+	—	+
16	++	—	—	+	—	—	+
17	++	—	—	++	++	—	—
18	++	—	—	++	—	—	+

Additional observations are:—

(1) Fever was recorded only in three cases. The fever of Case No. 2 appears to have been malaria.

(2) Oedema was the special feature of every case, the first to appear and the last to disappear.

(3) Knee reflexes varied, sometimes being quite absent but normal a few days later, and vice versa. Absence of reflexes is recorded in all cases in which it was found at any time.

(4) The urine was in all cases albumen free.

(5) A delayed second cardiac sound was observed in a number of cases. Some cases complained of palpitation.

Course of the Disease.—The disease was not a disabling one. Several cases were confined to bed for a few days, but the majority recovered in three weeks without any change in diet.

Case No. 1 was the most serious. In spite of three weeks holiday in September, she returned to Kalna on account of her illness. Latterly she had blurring of the vision, due probably to a toxic paresis of the iris muscle. She ultimately recovered on 14th October.

Treatment.—Very few cases required treatment, the disease being accepted by the people as one which got better of itself. Four of the cases required to be admitted to hospital. With absolute rest, daily injections of adrenalin, and a mixture containing digitalis and iodides, they made a slow recovery.

Case No. 9. This case requires special comment as she died suddenly while suffering from beriberi. On 2nd September, 1926, at 5 p.m. she complained of palpitation, and an assistant, finding her heart very fast, prescribed a sedative mixture. She did not complain of beriberi then. Till 9 p.m. she was well and then went to bed. I was called at 1-30 a.m. and arrived to find that she had just died. Before her death she had vomited twice and she had had increasing difficulty in respiration. Previously she had been a healthy girl of nineteen, and there was no apparent reason why she should thus die suddenly. On investigation it was found that she had been suffering from beriberi for about fifteen days. From the description of those who were with her before her death we are inclined to think that she died from œdema of the lungs. Post-mortem examination was not made, but the froth at the mouth and nose at the time of death, and a continual watery discharge from the nose and mouth till she was buried twelve hours later, also suggest œdema of the lungs as the cause of death.

Rice Supply.—We made a careful investigation of the rice supply. The map illustrates the area in which the Mission compound is situated. There is one shop in this area, and from it most of the people living in the Mission compound and round about obtain their rice. The majority of the customers buy small quantities of rice at a time. Some eat milled rice only, some home-prepared rice, while others, who are not particular, sometimes eat one and sometimes the other. The whole stock of rice kept in the shop is five or six bags and this is sold out in about ten days; the stock being renewed about every tenth day. All this rice is bought locally from

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the rice merchants in Kalna. Throughout Kalna are numerous other such shops, all drawing their rice supply from the same sources.

Discussion.—This outbreak occurred exclusively amongst the Mission workers at Kalna. It was a small outbreak relatively and, on this account, detailed observations could be made.

In view of the fact that the theory of infected rice as the cause of epidemic dropsy holds the field at the present time, we naturally made a careful investigation of the rice supply in order to see if it had any connection with the incidence of the disease, and if so, what factors there were which limited the size of the epidemic. Obviously, there was no widespread infection of rice in this district, as no cases except those reported were sent to us or heard of at the time. In the town of Kalna itself (population 8,000) not a single case occurred. On the 6th September, three cases of epidemic dropsy came from a village sixteen miles away in district Nadia. They reported that there was an outbreak there. The people of Kalna buy their rice from small shops which, in turn, buy rice from the rice merchants in Kalna, that is from the same source as the rice supplied to the Mission workers at Kalna.

One might presume that only a limited amount of rice was infected and, being bought by some of the Mission workers, the disease occurred amongst them. In this outbreak, there were persons of nine households who developed epidemic dropsy. These nine households all bought their rice from the one shop. The same shop supplied rice to sixty households altogether; of these thirty are within the Mission and thirty outside, but close to the Mission. On investigation, we found that there was no period in July and August when only infected persons bought rice. Some of those who suffered from the disease were supplied only with home-prepared rice, some with milled rice, and some with both. Of those who were not affected the same facts can be recorded. We see, therefore, that there was no general infection of the rice sold at the shop.

Again, one may presume that only one bag of rice was affected and by some unlucky chance this rice was supplied to the Mission customers. Our investigations prove however that this was not possible, as there was no period during which these nine households alone were supplied in close succession. This supposition is also disproved by two other facts: (1) the rice supply lasted for ten days, yet fresh cases occurred long after that rice supply should have all been sold; (2) case No. 18 had been on holiday and arrived on Kalna on 4th September. She developed the disease on 7th September. The rice supply of this household had been renewed but a few days previously. This investigation effectively disposes of the theory of infected rice as being the cause of the disease in this outbreak. We failed to find any connection between the rice supply and the incidence of the disease. Our observations tend rather to disprove this theory.

The really striking points about this outbreak are these two facts: (1) that the outbreak occurred within a few days of the arrival in Kalna of people suffering from the disease, and (2) that there are definite indications of a person-to-person infection through the whole series of cases. (*See* Table III.)

TABLE III.

House-hold.	Case No.	Age.	Sex.	Occupation.	Date of onset.	Relationship to other cases.
A.	1	21	F.	Housekeeper	1-8-26	Mother of imported case No. 4. Imported cases lived two nights at A.
B.	2	42	F.	Ditto.	9-8-26	Imported cases lived with her at B.
C.	3	50	M.	Cook ..	12-8-26	Continuous mixing with imported case No. 5.
D.	4	40	F.	Nurse ..	12-8-26	Mixed much with imported cases and with No. 1.
A.	5	28	M.	Doctor ..	15-8-26	Lived at A.
E.	6	23	F.	Teacher ..	15-8-26	Sister of imported case No. 1. Visited A often
D.	7	24	F.	Nurse ..	17-8-26	Lived with No. 4 and had same relationships.
D.	8	22	F.	Nurse ..	17-8-26	Ditto.
F.	9	19	F.	Teacher ..	18-8-26	Ditto.
E.	10	19	F.	Teacher ..	18-8-26	Lived with No. 6. Visited A often.
E.	11	21	F.	Teacher ..	18-8-26	Ditto.
C.	12	11	F.	Schoolgirl ..	18-8-26	Daughter of No. 3.
C.	13	8	F.	Ditto. ..	20-8-26	Ditto.
G.	14	28	M.	Servant ..	20-8-26	Mixed much with No. 3.
H.	15	14	F.	Schoolgirl ..	1-9-26	Mixed much with nurses in hospital.
I.	16	25	F.	Housekeeper	1-9-26	Sister of No. 9. Visited her often.
F.	17	55	F.	Cook ..	4-9-26	Mother of No. 9.
H.	18	55	F.	Biblewoman..	7-9-26	Lived with No. 15. Mixed with nurses much.

The infection is seen entering at three points:—

I. Imported cases Nos. 1, 2, 3 and 4 came to Kalna on the 27th July and lived at "A" for two nights. On the 1st August local case No. 1, living at "A," developed signs of beriberi.

II. On the 29th July imported cases Nos. 1, 2 and 3 went to live at "B." On the 9th August local case No. 2 occurred at "B."

III. On the 2nd August imported case No. 5 arrived in Kalna and was admitted to hospital. He spent a great deal of his time with local case No. 3, who developed beriberi on 12th August.

From these three points of entry we can trace two lines of person-to-person infection amongst the people infected:

1. Cases Nos. 1 and 2 were both females and from them the disease is seen spreading through the women in the Mission compound. Not all the women in the compound were affected—only those who mixed much with infected cases. In this line of infection is found one male, case No. 5, who was living at "A." He was away for the two nights when the imported cases lived at "A," but imported case No. 1 occupied his bed for these two nights.

2. Case No. 3 developed the disease on 12th August. His two daughters Nos. 12 and 13 developed it on 18th and 20th August respectively, and then case No. 14, with whom there was contact, also on 20th August.

A great deal could be written about the contact of case with case. A study of Table III and the map however will show how the cases were connected.

More important is it to point out how, when there was no close contact with infected people, cases did not occur:

(*a*) The sweepers were separate—no beriberi.

(*b*) One female nurse did not have beriberi. She lives at her father's house—not with the nurses in hospital—and comes for duty. It is worthy of note that her rice is supplied from the same shop.

(*c*) A number of miscellaneous people, servants, etc., who work in the Mission but live outside did not develop the disease.

(*d*) Male teachers and compounders did not develop the disease. They had no contact with the women nor with the other line of cases. Case No. 3 however cooked for several of them, but there was no contact between him and those for whom he cooked, as he placed the food on dishes with a ladle after cooking it.

On the other hand there were a number of persons whom we would have expected to have become infected with the disease but who did not become infected. We record below under the different cases instances of people who were in close contact with cases, but did not develop epidemic dropsy.

Case No. 1. Her husband and daughter did not develop the disease. The former was himself a patient in hospital for the first month of the two and a half months of his wife's illness, but she visited him often.

Cases Nos. 3, 12 and 13. The wife of case No. 3 and mother of cases Nos. 12 and 13 did not contract the disease.

Case No. 14. The wife of this case was not infected.

Cases Nos. 15 and 18. A Biblewoman who lived with these cases remained free of the disease.

Case No. 16. Her husband did not develop the disease.

Imported case No. 3. A compounder was a special friend of this case but remained free of the disease.

SUMMARY.

The article describes a small localised outbreak of epidemic dropsy which has several striking features:

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(1) The outbreak occurred in a place where previously there had been no sign of the disease.

(2) It followed immediately on the arrival of people suffering from epidemic dropsy.

(3) There was no apparent connection between the rice supply and the incidence of the disease.

(4) There was evidence of a person-to-person infection.

(5) Instances of non-occurrence of the disease where it might have been expected to occur, if it were infectious are recorded.

TWO FORMS OF INFECTION OF THE KIDNEY.

By SIR JAMES R. ROBERTS, C.I.E., M.B., M.S., F.R.C.S. (Eng.), I.M.S. (Retd.).

Staphylococcal Infection and Perinephritic Abscess.—This has a direct relation to an attack of *boils*, and is an infarct of the cortical portion of a lobule or adjacent lobules and does not affect the apical portion. The immediate portion of the lobule under the capsule becomes the seat of a small abscess which burrows into the perinephritic tissue, and a large abscess results. This then is the most common cause of perinephritic abscess: less common causes are stone and guinea-worm, but these are more chronic in their development. This staphylococcal abscess is not necessarily associated with pus and blood in the urine, as it is likely to be shut off from the rest of the renal tissue. We see many cases of abscess in the cellular planes of the body following boils, and this infection of the cortex of the kidney is another example. The symptoms are rigors and fever of an acute type with pain in the loin, and subsequently a large swelling or tumour to be felt in the loin. It is important to diagnose the condition in an early stage remembering its association with boils and to open the abscess early, before too serious injury has been produced and before the general health is gravely involved. Pressure upon the lumbar plexus produces pain in more distant parts and adds some obscurity; hence it is well to remember this point. *Treatment* by incision and drainage requires no special description.

Bacillus Coli Infection.—There are two forms, the acute and the subacute, which latter passes into a chronic infection. The *acute* is rare, in fact very rare. It is an intense infection of one kidney with hæmorrhagic infarcts and general congestion and inflammatory œdema of the kidney tissue. This gives rise to marked hæmaturia. The important aspect of such a case is the sudden onset with rigors and the patient is brought from normal health in a few hours or a day to a condition bordering on death. The collapse is intense; the fever is high; vomiting is present; with great pain in the loin: enlargement of the kidney is to be felt unless the patient is obese, and there is the hæmaturia to guide in the diagnosis.

How is this acute condition to be dealt with? Either by the treatment given to a subacute case in the hope that the patient may be tided over the crisis and the acute inflammation of the kidney subside to a chronic one, or *immediate excision* of the kidney has to be most seriously considered, in spite of the collapse, as there is not much time available before the patient succumbs. However, these cases are so rare that a practitioner of long experience may never meet with such a condition.

Subacute Bacillus coli *Infection.*—Here again one kidney is attacked. The onset of the subacute type is fairly rapid, is apt to follow exposure to cold; rigors and fever are marked, with pain and tenderness in one loin, and the hæmaturia at once directs the attention to a kidney condition. In fact it is one of the more common causes of hæmaturia of the kidney type. Nausea and vomiting are present with the usual symptoms of severe illness on tongue, bowels, appetite, etc. An examination of the urine for *Bacillus coli* will give further information and decide the diagnosis. The infection attacks the apical portions of the lobules and the pelvis of the kidney, and not the cortex.

The recognition of this infection, in order that the treatment shall prevent the disease becoming chronic and intractable, is most important, as in this subacute condition treatment is successful, except perhaps in those past middle life. The essence of the treatment is to produce alkalinity of the urine as quickly as possible by large doses of citrate of potash, one drachm every four hours or every three hours, and the testing of each portion of urine passed with litmus paper so that when alkalinity has been obtained the doses of citrate of potash can be reduced sufficiently to maintain this condition. We all know that the *Bacillus coli* does not grow in alkaline media. Hot fomentations to the loin must be assiduously applied and the bowels evacuated at once by castor oil if the nausea or vomiting will allow of this; if not by calomel and salines. A most important point is that the patient must remain in bed for three weeks at least with continuous treatment, otherwise the infection will become chronic. One may say that had all cases been treated in the early stage, we should see few chronic ones. Rest is most essential. Naturally a bland diet has to be ordered, as in all cases of nephritis.

Chronic Bacillus coli *Infection.* This condition is so common in India and is the cause of the wrecking of so many important lives that it is time we should be able to effect a cure with the advance of medical science.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Subacute or mild cases are of very frequent occurrence in children, but the resilience of the tissues of the young is such that Nature effects a cure with or without special treatment. In cases of febrile disturbances in children it is as well to bear *Bacillus coli* infection in mind and to remember the connection between the *coli* group and the typhoid group both of which infect the urine, which really means the kidney. The subacute infection passes into the chronic by recovery of the kidney tissue, but the continued infection in the pelvis remains and subsequent bladder irritability in some cases occurs. With this condition of pelvis infection relapses accompanied by fever, hæmaturia, etc., are common enough, even passing to a fatal issue. It is remarkable, however, that chronic pelvic infection may go on for years with few if any symptoms or only those of temporary derangements, the general health being in some affected, in others not at all. It is fortunate that the pelvis of the kidney is the residual focus and not the kidney tissue, otherwise the measures advocated below would have no chance of success. I have often thought that it was *Bacillus coli* infection which is the initial cause of stone in children of the tender ages of two, three and four.

Whether the *Bacillus coli* infecting the kidney is one of the human varieties or not is a question requiring investigation, or whether there is an extraneous and animal source. If it were human everyone should become infected: if its source is the cow the result would be similar. Is it the dog or what? Is there a scale of these bacilli with the typhoids at one end, and human *coli* at the other? The varieties of *B. coli* are numerous; some pathogenic to man, others not.

In the treatment of chronic *B. coli* infection of the kidney, urinary antiseptics by the mouth have failed or only ameliorate, vaccines have conspicuously failed, though temporary improvement has resulted. I have known cases of heavy infection only kept going by doses of vaccine from time to time. It is no use injecting the bladder with antiseptics as the disease is not located there.

Now comes an important advance; it is the pelvis of the kidney that requires to be injected and washed through a ureteral catheter and this must become the universal practice. There is no reason why a hospital surgeon in India should not become expert in the use of the cystoscope, the introduction of ureteral catheters, and lavage of the pelvis of the kidney. It is a question of apparatus, with its syringe, and a textbook on genito-urinary surgery: the material to practise on is in abundance. Anæsthesia is however essential.

The question of the antiseptic to be used for this lavage has to be considered. At present those practising it are in favour of silver salts,—silver having an old established reputation in genito-urinary surgery. There is nitrate of silver; collosol silver; argyrol; protargol, etc.; there is flavine 1 in 5,000; boric acid; carbolates; alkalies; the mercury salts; in fact this portion of the technique can be worked out by each practitioner according to his tastes. The essential point however is to use such as effect a cure in from 4 to 6 washings of the pelvis of the kidney. If it does not it is valueless. At last it appears that there is hope, the cure of these cases is at hand; treatment so far has been a sad failure and a patient with chronic infection of the pelvis of kidney has never been certain of his future. Where some stricture of the ureter exists relapses are likely to occur, and, further, cases of floating kidney with kinking of the ureter must undergo an operation for replacement before cure by lavage can become effective.

THE CONTROL OF KALA-AZAR ON TEA ESTATES.

By L. EVERARD NAPIER, M.R.C.S., L.R.C.P. (Lond.),
Kala-azar Research Worker, Calcutta School of Tropical Medicine;
and
PERCY FOSTER, M.R.C.S., L.R.C.P. (Lond.),
Badlipar, Assam.

PROPHYLACTIC measures that have been adopted with any success are:

(*a*) Segregation of sick and contacts.

(*b*) Transfer of the whole population to a new site.

(*c*) Intensive treatment.

(*a*) This measure aims at the removal of the source of infection. The failure is partly due to the fact that the early stages of the disease are very difficult to recognise and partly to the fact that the patient has every encouragement to conceal his symptoms if his failure to do this will mean the expulsion of himself and his family from his home.

(*b*) This measure is aimed at the removal of the population from the site wherein lies the agency that transmits the infecting organism from man to man. The hope of success is dependent on the assumption that the transmitting agency will not be transferred with the population and will not readily establish itself in a new site; the infecting cycle will thus be broken. The apparent failure of this measure is due to the fact that it is frequently many months, in some cases more than a year, after infection takes place before the first symptoms of the disease are apparent, so that persons who appeared to be infected on the new site were really infected on the old one. The actual failure of this measure is due to the fact that both recognised and unrecognised cases may linger on

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

for so long that in the meanwhile the conditions in the new site become suitable for transmission to occur again and the broken cycle is mended.

(*c*) This measure also aims at the removal of all source of infection. It is dependent on the assumption, probably a sound one, that a person placed under proper treatment ceases to be infectious. Its failure is dependent on the fact that it only leads to the removal of a part of the source of infection, namely, the clinically obvious cases, and leaves untouched the unrecognised cases; it is inferior in this way to segregation which removes also the contacts amongst whom the largest number of unrecognised and early cases are likely to be found. Its partial success in practice is dependent on the fact that the promise of treatment will lead to the discovery of the early cases which the threat of segregation would fail to bring to light.

In the days prior to the introduction of antimony in the treatment of kala-azar measures (*a*) and (*b*) were given a very thorough trial; those who had an opportunity of observing the effects of these measures, Rogers (1899), McCombie Young (1924) and others, were unanimously of the opinion that the former was of little value, but that the latter, though more difficult and expensive to carry out, could be relied upon to control an epidemic in a village or tea garden coolie force.

Since the introduction of antimony in the treatment of the disease and more especially since the introduction of the more successful pentavalent compounds, it becomes necessary to re-examine the whole position with regard to the preventive measures to be adopted in a community into which the infection has been introduced.

Dooria.

One of the writers (P. F.) working in the Golaghat district in Assam has had the opportunity of seeing the disease occurring in epidemic form in a number of tea gardens under his charge. In one garden, Dooria, cases of the disease were first observed in 1916; within 2 years 350 persons, or 20 per cent. of the original coolie force, became infected and as little was known of the antimony treatment in those days more than half of these died. It was some time before the gravity of the situation could be impressed upon those who held the purse-strings and even then new lines had to be built, so that it was some considerable time before a transfer could be effected; this actually occurred in March 1918. The effect of the transfer is seen in the accompanying graph—Figure I—which is based the case incidence month by month.

FIGURE I.

The transferred coolies were arranged into three groups:—

A. The infected line, i.e., households in which there was a definite case of kala-azar.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

B. The contact line, i.e., households in which there was a suspected case of kala-azar, or had recently been a case.

C. The uninfected line, i.e., households from which no case of kala-azar had been reported.

It will be seen from the graph that there was a very marked falling off in incidence from the time of the transfer of the lines. Experience has shown that the highest point in the onset curve occurs in the cold weather months, November to February. On this tea estate in 1917, the largest number of cases were "listed" in the months of March, April and May. In the following year, as both the medical staff and the coolies themselves were more familiar with the disease, it is natural that earlier diagnosis would be the rule; it is therefore not surprising to find that the largest number of cases were "listed" in January in 1918. The fall in the incidence during the few months following the transfer is not a matter of much importance, but the failure of the incidence curve to rise to any height comparable to that of the two previous rises during the next cold weather and the garden's subsequent complete freedom from infection are points of great significance.

At this time the antimony treatment of kala-azar was in its infancy. No antimony treatment was given during 1916, but during 1917 about three-quarters of the patients were treated with potassium antimony tartrate. This treatment was neither very successful—only about a 33 per cent. cure rate being attained—nor very popular, so that during the following year only about one quarter of the patients underwent this form of treatment. It therefore seems impossible that the treatment could have influenced the course of the epidemic to any extent.

The fall in the incidence and subsequent disappearance of the infection must have been brought about in one of two ways; either the epidemic had "burnt itself out," i.e., all the susceptible persons had become infected, or the transfer of the lines stopped the spread of the infection. If in the former way, then we should expect the epidemic to burn itself out first in the most heavily infected line and the fresh cases to crop up in the lines which had hitherto been comparatively free from infection; this is the reverse of what actually happened. During the ten months subsequent to the transfer 47 out of 642, or 7.3 per cent. of the population, of the inhabitants of the infected line, 15 out of 310 of the inhabitants, or 4.8 per cent. of the population of the contact line, and 8 out of 345 of the inhabitants, or 2.3 per cent. of the population, of the uninfected line became ill with kala-azar. On the other hand there is considerable support for the suggestion that the transfer stopped the infection of more persons: 36 of the 47 cases in the infected line occurred within 3 months of the transfer of the lines; in these cases the infection certainly occurred previous to the transfer. It is known that the incubation period may be more than a year in certain instances, it is therefore quite possible that all the patients showing symptoms subsequent to the transfer were actually infected previous to the transfer.

One is driven to the conclusion that the almost dramatic cutting short of the epidemic was due to the transfer of the lines.

Hautley.

On another tea estate which had been apparently free from the disease prior to this date a number of cases were diagnosed in 1921; on this estate the coolies were living in two sets of lines, the "factory lines" and the "out lines." Different measures were adopted in dealing with the disease in the two sets of lines. In the "out lines" segregation measures were adopted; as each case was diagnosed the patient and the whole household were removed to the "factory lines." At this time treatment with sodium antimony tartrate was giving very satisfactory results; all the cases were placed under treatment immediately so that there was every encouragement for the sick coolies to come forward, and it may be said that segregation was carried out under almost ideal conditions.

In the other lines, "the factory lines," no segregation was carried out, but each case that was diagnosed was immediately put under treatment. When the epidemic developed serious proportions it was decided that the lines should be transferred. This transfer was not carried out at one time, as in the case of the other estate, but the families in which no cases had occurred were transferred to the new lines as they became ready for occupation; subsequently the contacts, i.e., the families in which cases had occurred but were cured or had died, were transferred; and finally, the old lines were abandoned and all the kala-azar patients together with their families were transferred to a new line. The transfer was commenced in July 1922 and completed in September 1923.

Figure II shows the actual incidence of cases month by month in the two gardens and the apparent effect of the transfer of the lines in the factory garden.

Of the contacts, 142 in all, which were removed from the "out lines" to the "factory lines" 29 developed kala-azar; as two-thirds of these developed the disease within 3 months of transfer and all except three within a year, it is probable that the majority of these became infected in the "out lines" although they did not develop symptoms until after they were transferred.

At the end of 1921, the population of the "factory lines" was 1,197 and that of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

"out lines" was 1,581; in the former 289 cases of kala-azar, of which 29 were amongst the imported contacts, occurred and in the latter 80 cases occurred during 4 years; so that of the original force of the former garden 260, or 22 per cent. became infected and of the latter 109, or 7 per cent.

FIGURE II.

Let us first consider the effect of the measure adopted in the "factory lines." For the first year treatment alone was relied upon. This measure was apparently not very successful; a more careful examination of the data will however reveal the fact that it was not such a complete failure as the first glance at the figures appears to suggest. The first cases were noted in May 1921, then during the subsequent months an increasing number were listed each month; this state of affairs led to a thorough examination of all the members of the coolie force which in turn resulted in the revealing of a large number of cases in the month of September. It is very probable that most of these patients had been suffering from kala-azar for some time—as in most instances the aldehyde reaction was well developed—so that they had been a source of infection during the greater part of the year and certainly during the early part of the monsoon season, the period when it is probable (Napier, 1926) that the largest number of infections occur. Treatment at this point was merely closing the stable door when more than half the horses had escaped, consequently at the beginning of the next year another crop of cases appeared. During the next year the transfer of the lines was commenced so that the effect of treatment alone was overshadowed. The result of the combination of treatment and transfer of the lines was that during 1924—the year after the transfer was complete—the incidence in the garden fell to 14 and subsequently no cases have occurred.

In the other garden, the "out lines," the evidence suggests that the epidemic had not established itself prior to its discovery as in the case of the "factory lines," as in September when 36 cases were discovered in the other garden only two were discovered in the "out lines." There is, however, no reason to suppose that the epidemic would not have developed the same proportions in time had not measures been adopted to stop it. Figure II shows the partial success of these measures. It will be seen that despite the removal of all patients and contacts, cases continued to crop up for a considerable time; in 1924 when only 14 cases were listed in the other garden, there were 22 new cases listed in these lines and even in 1925 new cases were appearing. Such success as followed these measures was undoubtedly due to the fact that they were adopted from the very beginning of the epidemic; the failure to stop completely the spread of the disease is due to the fact that *segregation of the cases and contacts even when*

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

combined with treatment, does not remove the whole source of infection.

CONCLUSIONS.

The conclusions that one draws from the experience in these two gardens is that by segregation and treatment alone the spread of the disease in an estate will not be stopped, but that by these measures it can be controlled, especially if they are adopted early (*vide* Hautley "out lines"); that a lesser degree of success can be expected from treatment alone (*vide* Hautley "factory lines," early measures); and that transfer of the lines can be expected completely to cut short an epidemic (*vide* both Dooria and Hautley "factory lines," later measures).

Whether or not it is advisable to advocate transfer of the lines in view of other considerations is an entirely different matter. It is seldom possible to carry out a complete transfer in less than one year, by which fact the value of this measure is considerably reduced. Furthermore, it is extremely unpopular amongst the coolies and is very expensive. On the other hand, the treatment of the disease is so satisfactory in these days that a 95 per cent. cure rate can be anticipated and the cost even for the more expensive pentavalent compounds can be calculated at about Rs. 5 per patient in a mixed population. Treatment would of course be carried out even if the lines were transferred, but it is doubtful even at a most pessimistic estimate if the failure to transfer the lines could lead to more than 200 additional infections per 1,000 of the population; the additional actual cost, Rs. 1,000, for the treatment of these cases would most certainly be much less than the cost of transferring the whole line.

Taking all things into consideration, therefore, the obvious policy to adopt, unless there are independent reasons for the transfer of the lines, is treatment of each case as it arises. If this is combined with repeated inspection of the coolies and careful observation of all suspicious cases and contacts a considerable degree of success can be anticipated.

Note. One of the writers (P. F.) has had an opportunity of applying these conclusions practically. On one garden under his medical control, 23 families and on another 16 families became infected with kala-azar during the years 1923, 1924 and 1925. All the patients were placed under treatment with urea-stibamine but no other preventive measures were adopted; in only 6 and 2 instances, respectively, have second cases occurred in these families.

CORRIGENDUM.

A Mirror of Hospital Practice.

A CASE OF CEREBRAL ABSCESS AND ONE OF TUBERCULOUS PERITONITIS.

By M. UMAR,
5, *City Road, Allahabad.*

Case 1.—Durga, prisoner in the Bareilly Central Jail under section 395, *Indian Penal Code*, came to the hospital with fever, and quite unable to lift his right upper extremity. There was no loss of sensation to heat, cold and touch, neither was there any wasting of muscles. He was admitted on the 1st July 1923. On the 13th he could not speak a word and paralysis of the right arm and leg was complete.

There was slight headache (not very severe). He died at 12-30 midnight on the 15th July. There was no other symptom beyond those recorded above..

Post-Mortem Examination.—Body thin and of poor physique; dura mater adherent to the brain substance over the left lateral lobe. The left lateral lobe on section showed an abscess cavity containing about six ounces of pus which was thick, grumous, and darkish blue in colour. Other organs were normal.

I regret that no bacteriological examination was made in this case.

Case 2.—This patient was transferred to the Bareilly jail from the Andamans without any history whatsoever. It was written on his papers that the transfer was "on medical grounds."

His name was Itwari (probably born on Sunday). He was in a very bad state of health with enlargement of the spleen and liver. The heart sounds were weak. The spleen appeared to be much below the umbilicus and there were signs of bronchitis in the lungs. He was also anæmic. Oedema had commenced in both his feet and there was an afternoon rise of temperature up to 101°F.

Naturally he was treated with the most favourite drug in India, viz., quinine, but it proved of no use. After some time he began to pass both mucus and blood. I examined the stools under the microscope for amœbæ, but the result was negative. I also examined the sputum repeatedly for tubercle bacilli, but this result was negative also. The urine shewed traces of albumen. On the 28th July œdema was much increased. He died on the 9th of September at 9 p.m.

He was sentenced on the 17th November 1919, came to this jail on the 19th February, 1924, and was admitted to the hospital on the 24th June 1924.

Post-Mortem Examination.—The whole of the great omentum was very much thickened, so much so that it gave the appearance of an enlargement of spleen; also it was brittle.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The large and small intestines were matted together absolutely in such a way that it was impossible to separate them, but they could be moved *en masse* like a football. There was a darkish red growth from the left to the right iliac fossa through which all the small intestines were attached to the pelvic brim and could only be separated by the aid of a knife. There was reddish fluid in the abdomen. The spleen was enlarged, but not so much as was suspected during his lifetime. Its weight was 24 ozs. It was concealed by the great omentum. The heart was fatty, and both lungs were congested and shewed pleural adhesions.

A piece of the great omentum and the growth from the small intestine was forwarded in spirit to the Central Research Institute, Kasauli. The report from the Central Research Institute, dated the 27th September is as follows:—The following is the result of the examination of omentum and growth from the small intestines taken from prisoner No. 1244, Itwari. Sections made from the material sent show chronic inflammatory conditions. They show cells of the inflammatory type with a large amount of formed fibrous supporting tissue. Throughout the sections are to be seen fairly extensive areas of necrosis and associated with many of these there are to be seen giant cells with peripherally situated nuclei. In these areas of caseation relatively numerous acid-fast bacilli were found. The blood vessels are not numerous, but are for the most part well formed and in some cases actually markedly thickened. There is no evidence of malignant disease and the condition is one of chronic infective granuloma of tubercular origin.

A CASE OF ARSENICAL DERMATITIS FOLLOWING INJECTIONS OF NOVARSENOBILLON.

By B. P. BANNERJI, M.B.,
285, *Kalighat Road, Calcutta.*

THE patient, a Hindu male adult, came to me for medical advice with a small hard chancre on the prepuce and a history of exposure to infection. Otherwise he looked healthy and stout, and gave no history of any previous severe illness. Accordingly, I tested his urine with negative findings, and gave him an initial dose of 0.3 gm. of Novarsenobillon. The reactionary symptoms were negligible, and he appeared to be doing well.

The second dose—0.45 gm.—was given on the eighth day of treatment, and the third dose—0.6 gm.—ten days later. As the injection made very little impression on the sore, and as the patient was impatient and asked for intensive treatment, a third dose—of 0.9 gm.—was given on the twelfth day after the third injection. In the meantime he was having local applications to the sore.

Immediately after the fourth injection he had a severe rigor, and the temperature rose to 103°F., with severe headache and nausea. These reactionary symptoms however abated within twenty-four hours. As ill luck would have it however, there was no appreciable change in the ulcer, and the patient became more insistent than ever on intensive treatment.

Up to this date he had shown no symptoms of intolerance to arsenic, and accordingly a fifth dose—of 0.9 gm.—was given ten days after the fourth injection. This time the reactionary symptoms were severe and on the third day after injection he developed intense jaundice and a maculo-papular rash all over the body, with excruciating pain and pruritus. Gradually his whole body swelled up, the mouth became full of aphthous patches, and fever continued without intermission. There was nausea and vomiting at times and he had complete loss of sleep and appetite.

The case appeared to be clearly one of arsenical dermatitis following on Novarsenobillon injections, with symptoms of acute yellow atrophy of the liver, and he was treated by a saline mixture orally and calamine lotion externally. Absolute rest was prescribed and a regulated diet. He gradually began to improve, and later Acnetox was given, which acted like a charm, and all the skin lesions subsided. He was subsequently given a general tonic and made an uninterrupted recovery.

A CYSTIC TUMOUR OF THE MESENTERY.

By J. B. VAIDYA,
MAJOR, I.M.S.,
District Medical Officer, Kurnool.

A MARRIED woman, aged about 30 years, was admitted to hospital for a tumour in the abdomen. The history was of one year's duration. The patient first noticed a swelling in the right lumbar region, which gradually increased, and she had irregular fever. On admission the tumour was found to occupy practically the whole of the right side of the abdomen from the pelvis right up to the under surface of the liver. It also extended across the middle line to the left, but not to such an extent as on the right side. The left iliac region was however resonant. A diagnosis of ovarian cyst was made and the abdomen opened in the middle line. The cyst was tapped and five gallons of a dirty brownish fluid came out. On exploring it was found that the cyst did not arise in the pelvis. The ovaries and broad ligaments were normal and well away from the tumour. The cyst was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

lying in the position of the leaf of the mesentery. Upwards it extended to the under surface of the right lobe of the liver and appeared to have pushed it to the left, since the gall-bladder was lying to the left of the middle line. Below, it extended to the brim of the pelvis on the right side. To the left it did not extend much beyond the vertebral column after it was empty. The intestines were pressed down. The cyst appeared to be in connection with the mesentery. The cyst was closed by two layers of sutures and the abdomen closed by through and through silk sutures. The temperature showed a rise, now and then, a week after operation. No malarial parasites were found in the blood, but after big doses of quinine the temperature did not show any rise. Soon after the operation she had diarrhœa, and about seventeen days after operation she passed blood and mucus in the stools for a couple of days. About three weeks after the operation the patient suddenly had diarrhœa and passed big motions which seemed to have the same sort of colour and appearance as the fluid withdrawn from the cyst at the time of the operation. It was curious to notice that the abdomen, which had been slowly filling up and was distended, became emptied out and no distension could be seen. The patient died a fortnight later as a result of parotitis and exhaustion. The abdomen did not show any signs of distension.

AN INTERESTING CASE OF FRACTURE OF THE SKULL AND INJURY TO THE BRAIN, ENDING IN COMPLETE RECOVERY.

By S. R. INGLE,

Medical Officer, Karjar, Colaba District.

A WELL-BUILT man aged about 30 was brought to this dispensary by the police on 3rd June 1926, for treatment of injuries he had received in a scuffle on 2nd June 1926. The injuries were said to have been caused by a *farsi* (hatchet) and sticks.

There were about eight wounds on his body. Of them the injury over the right parietal bone was serious. It was an incised wound measuring about 4½ inches in length, which had chipped the bone and caused damage to the brain. On examination of this wound three pieces of bone and about one drachm in weight of brain matter were found at its bottom. The cut was a slanting one. No wound of the dura mater, whence the brain matter might have escaped, could be detected. Owing to the sloping nature of the cut, the dura mater, I believe, might have been slit open underneath the bone and consequently the wound of the dura mater might have escaped detection.

Condition on admission.—The patient was conscious and remained so throughout his stay in the dispensary. His pupils were normal, pulse 90 per minute and regular, respiration 24 per minute and regular. There was no bleeding either from the nose or ears, and no paralysis. The temperature was 98°F.

Treatment:—The scalp was shaved round about the injuries, cleansed with 90 per cent. alcohol and then painted with tincture of iodine. After having removed the pieces of bone from the wound, it was gently irrigated with tincture of iodine (1 drachm to a pint), swabbed with B. I. P. P. and sutured, leaving in a piece of iodoform gauze as a drain. The remaining wounds, except two on the left side of the head, were similarly treated but closed without drainage. The usual dressings were applied, and the head bandaged. The patient was put on to the following mixture.—

Hexamine	..	10 grs.
Aqua	..	1 oz.

Sig:—Every 4th hour in a half-cupful of water.

This mixture was ordered with a view to preventing sepsis of the brain and meninges.

4th June 1926, 8 a.m. Temperature normal, pulse 80 per minute, no paralysis, no headache. Patient quite conscious, wounds clean. Gauze drain removed and the wounds redressed.

The subsequent history of the case was uneventful. The patient was discharged cured on 24th June 1926.

I wish to mention here that I have found B. I. P. P. very efficacious in the treatment of such wounds. I have observed no ill-effects from its use in very extensive injuries. The wounds, if treated by it within twelve hours or so after their infliction and suture, heal up by first intention. The usual strength of B. I. P. P. is:—

Bismuth Subnitras	..	1 oz.
Iodoform	..	2 ozs.
Paraffin Liquid	..	1 oz.

but I always use it in the following strength:—

Bismuth Subnitras	..	3 drs.
Iodoform	..	3 drs.
Liquid Paraffin	..	1 oz.

This is stirred up well in a pot and boiled over the spirit lamp. On boiling it assumes a reddish brown colour. It is then ready for use.

The interesting points in this case were the following:—

(1) The remarkable absence of cerebral symptoms, even after fracture of the skull and injury to the brain.

(2) The absence of sepsis, in spite of the fact that the wounds were tied up by the patient with a dirty cloth and that more than twelve hours had elapsed since their infliction.

A CASE OF ASCITES CURED BY PERMANENT DRAINAGE OF THE FLUID INTO THE SUBCUTANEOUS TISSUE.

By D. N. KALYANVALA, M.R.C.S. (Eng.),
Chief Medical Officer, Porbander State.

A FEMALE patient, G. B., aged 35 years, was admitted to the hospital suffering from ascites. Her general condition was weak, the liver and spleen were very much enlarged, but the heart and kidneys were normal. Before her admission to the hospital, in spite of all medical treatment, she had been tapped eight times at intervals of about two weeks, and at each tapping nearly 20 pints of fluid were withdrawn.

Previously in similar cases I had tried artificial drainage by means of a short straight cannula and also by passing silk threads through the peritoneal cavity into the subcutaneous tissue of the groin, but after two or three weeks the fluid again began to accumulate.

For this case I devised a curved silver cannula about 2 inches long with two circular flanges at the curved end.

A semi-circular incision was made in the left iliac region and a flap of skin was turned down. The muscles were split by McBurney's method and an opening made into the peritoneal cavity. One flange of the cannula was inserted in the peritoneal cavity and a purse-string silk suture was passed through the peritoneum and tied tightly round the neck of the cannula between the two flanges.

In order to keep the cannula in position it was fixed to the muscles by means of silver wire passed through the holes in the outside flange. The straight end of the cannula pointing downwards was inserted in a pocket made in the subcutaneous tissue. The muscles were stitched together and the skin united by metal clips.

At the time of the operation I had left half the quantity of fluid in the peritoneal cavity. Later on this was evidently draining well, as on the third day after operation there was marked collection of fluid in the subcutaneous tissue of the left iliac region, groin, and vulva.

In order to remove the excessive pressure of the fluid I tapped the patient in the right iliac region and removed all the fluid. Compresses of lead lotion were applied to the swollen parts and the swelling rapidly subsided. The clips were removed on the sixth day and the wound was quite healed.

The operation was performed on the 11th June, and the patient was discharged on the 29th June, after keeping her under observation for 18 days. The patient's husband reported to me four months later that she was well and that there was no sign of the fluid refilling.

A CASE OF ANGIO-NEUROTIC ŒDEMA.

By EDMUND BURKE, L.R.C.P., L.R.C.S. (Ed.),
Medical Officer, Mangaldai Medical Association, Assam.

SIX weeks ago, Mrs. X, a European lady, while playing "bridge" in partnership with me, suddenly complained of intense itching and burning of the skin of the neck, arms, and shoulders.

This occurred twice more in the course of the next half-hour greatly irritating the lady who complained feelingly of these "awful attacks of prickly-heat."

However, shortly afterwards, large, tender, red and sharply-circumscribed swellings appeared on the patient's neck, back of the fingers, hands, arms and face, affecting the eyelids and lips, so much so that her features were greatly distorted. On sitting, the patient complained of pain and swellings of both buttocks also. The symptoms puzzled me at the time and, the diagnosis being uncertain, a soothing lotion was applied temporarily, and it afforded some alleviation of the irritation. Next morning all swellings had disappeared except some slight œdema which still remained on both hands.

The next night I was asked to see the lady as she was again affected by the same symptoms and was much distressed, as the lips were more swollen than on the night before. I learned that this attack occurred at almost exactly the same time (7 p.m.) as the first one. This time the patient remembered a similar, though infinitely milder, attack three weeks before when in Shillong—but never before that. There was no hereditary history of the disease. One or two members of the family had had skin troubles (acne, eczema) and rheumatism. The lady denied any irregularities of diet or susceptibility to any particular food. No gastro-intestinal disturbance occurred in this case in association with the above symptoms, though such manifestations are said to occur sometimes. From the character of the œdematous swellings and their periodicity and transient nature the above diagnosis was made. A hypodermic injection of adrenalin hydrochloride 1 : 1,000 m.x. was administered and in the space of an hour all symptoms had subsided. The lady remained well for a week, when another milder attack occurred (again at night and about 7 p.m.) but once more disappeared rapidly with the same treatment, and no more attacks have occurred since. The interesting feature of the case was its remarkable periodicity, the three attacks occurring at about 7 p.m. each time, as in Matas' case described by Osler (*Practice of Medicine*, 9th edition, p. 1115). I was gratified at the success of the adrenalin treatment, as the treatment of these cases is said to be unsatisfactory (Osler) and in my case it was largely in the nature of an experiment that I used the drug

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

mentioned. It is yet to be seen if the cure is permanent.

NOTES IN OPHTHALMIC PRACTICE.

By K. G. JAVA, M.B., B.S.,
Touring Medical Officer, Blind Relief Association, Tharparkar District, Umerkot, Sind.

THE following notes are the result of a year's experience as a touring medical officer engaged on ophthalmic work:—

(1) *The use of atropine before cataract extraction.* Whilst extracting cataracts by the intracapsular method, I found that eyes in which the pupil did not dilate after cocainization offered greater difficulty in the extraction of the lens than eyes in which dilatation of the pupil occurred. I therefore tried the effect of instilling a tiny drop of atropine (1 per cent. solution) before beginning cocainization, and have found that the extraction becomes considerably easier in such cases. I have only so far tried this on four or five cases, so cannot give any opinion as to the value of the method, but it appears to be worth a trial.

(2) *Cyanide injection for pannus.*—The injection of about 1 c.c. of a 1 : 2,500 solution of cyanide of mercury subconjunctivally gives such marked improvement in cases of pannus that I think the method to be worth further trial. The text-books recommend touching with copper sulphate for this condition, but this has not proved efficacious in my hands; in fact some of the cases appear to get worse.

(3) *Painting the lids with silver nitrate,* grs. 60 to oz. 1, for severe cases of trachoma has proved to be wonderfully efficacious. Of course any excess of this fluid must be at once removed by flushing out with normal saline.

(4) *Intravenous injections of iodine in a suppurating wound after cataract extraction.*—In two of my cataract cases the corneal wound suppurated. There was no panophthalmitis, but pus could be seen at the incision and a small quantity in the anterior chamber. I gave an intravenous injection of iodine (tincture of iodine 5 m. in 5 c.c. of distilled water), and the result was marvellous. The pus cleared completely in one case after one such injection, and in the other after two such injections. This suggests that intravenous iodine might be of use in the treatment of hypopyon ulcer also.

A NOTE ON THE STAINING OF TUBERCLE BACILLI.

By C. P. V. SHUNKER, I.M.S.,
Medical Superintendent, Central Jail, Bellary.

DR. A. D. GARDNER in the *Lancet* of 5th June, 1926, gives an account of his method of staining tubercle bacilli with picric acid as a counterstain instead of methylene blue. As there is a 40-bed tuberculosis annexe attached to this jail, there have been unusual facilities for giving the method a trial. During the last five months over a hundred examinations were carried out on the sputa of tuberculosis patients. In all these cases the stain has been found to be infinitely superior to the Ziehl-Nielssen's carbol-fuchsin method usually employed.

The method of staining is as follows:—A little of the sputum is placed on a glass slide and spread out into a thin layer and allowed to dry. It is then fixed by passing the slide through a spirit lamp flame. An oblong strip of filter paper cut to the size of the slide is then placed on the film and carbol-fuchsin poured on and heated over the spirit lamp till it steams. The placing of filter paper over the slide has the double advantage of holding up the dirt from the carbol-fuchsin and also retards the evaporation of the solution. The slide is then washed in water and the film is decolourised with 25 per cent. sulphuric acid solution in water. When the film has been almost completely decolourised it is washed in absolute alcohol and then in water. Then a half saturated watery solution of picric acid is poured on the film and allowed to remain for 5 to 10 minutes. The slide is then washed and dried and is ready for examination, which does not take more than two to three minutes to reveal tubercle bacilli, if there are any.

The above process is merely the substitution of picric acid for methylene blue as a counterstain. The advantage of the method lies in the fact that the red stained tubercle bacilli show up much better against a yellow background than a blue one and it appears to have the additional property of restoring the colour to feebly acid-fast bacilli, which would otherwise be invisible or unrecognisable.

In our series a certain number of cases admitted are labelled "tubercle bacilli negative," but tubercle bacilli were easily detected by the picric acid test. In many cases a comparison was made between the two methods from the sputum of the same patient and while Ziehl-Nielssen staining showed no tubercle bacilli or a few doubtful bacilli, the picric acid method showed large numbers clearly.

It is hoped that others will give this method a trial and find it as useful as we have done.

BERBERINE SULPHATE IN ORIENTAL SORE.

By R. L. VARMA, L.M.P.,
Ferozepore Cantonment, Punjab.

ORIENTAL sore—a disease which is very common in the Punjab—is very refractory to the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

forms of treatment usually advocated for it such as local applications of carbon dioxide snow, tartar emetic ointment, or antimony salts intravenously. Some of these renowned treatments are very costly and out of the reach of the poor type of patient and only available in big hospitals; others are so prolonged that the patient tires of the treatment before it is ended; whilst intravenous injections of antimony salts are not entirely devoid of danger.

In the year 1911, I remember to have read in the *Indian Medical Gazette* that the continuous application locally of *rasout*—a dry extract of *Berberis indica*—was found to be of benefit in some cases. I tried this on several cases, but without success. The results being so disappointing I discontinued this form of treatment, but a long time afterwards it occurred to me to try the alkaloid berberine instead. After dissolving ¼ gr. of berberine sulphate in 1 c.c. of distilled water and sterilising the solution, I infiltrated the sores of a patient with this solution by means of a hypodermic syringe. This was followed by some local reaction in the form of congestion and œdema, but with very little pain and tenderness, all of which subsided within four days. A week later I repeated the infiltration with the result that the patient was entirely cured, to my surprise and gratification. He did not require a third injection.

I have since followed this line of treatment in many cases without a single failure and am now led to believe that in berberine we have a specific cure for oriental sore, similar to that of quinine for malaria. Most of my cases have been cured by two—or at most three—local injections.

I suggest to my professional brethren in India that they should investigate this line of treatment. In the Punjab, kala-azar is almost entirely absent, and I have seen no case of that disease in the whole of my sixteen years of practice in the Province; but it is possible that berberine may prove a remedy suitable for injection in cases of kala-azar. I can only leave it to others to test this suggestion.

A CASE OF SEPTICÆMIA TREATED BY INTRAVENOUS INJECTION OF IODINE.

By B. L. CHOPRA, L.R.C.P., L.R.C.S., D.P.H., D.T.M. (L'pool),
District Surgeon, Lonavla

A PORTER from Shahbad was admitted into Sholapur Railway District Hospital on 28th July, 1926 suffering from a crushed right arm as a result of an accident at Shahbad on 27th July, 1926, at night.

His temperature on admission was 101°F and he was given 1,500 units of antitetanic serum. Constitutionally he looked a very weak individual and the condition of the wound was rather septic. He was operated upon by me the next morning. Amputation by the modified circular method was performed a few inches below the shoulder joint, and a drainage tube inserted. The following are brief notes of this case after operation:—

28-7-26. Temperature 102.5°F in the morning, and 103°F in the evening. One pint of saline given intravenously. Blood films examined for malarial parasites with negative result. 10 c.c. of anti-streptococcal serum given intramuscularly. He had a severe rigor in the evening: a further blood film was taken and examined but no malarial parasites found.

29-7-26. Temperature 104.6°F in the morning and 105°F in the evening. A further 10 c. c. of anti-streptococcal serum was given intramuscularly, and 2 pints of saline intravenously.

30-7-26. Temperature 103.8°F in the morning. At 1 p.m. a dose of 40 minims of iodine solution containing ½ grain of iodine was given intravenously. At 5 p.m. the temperature was 102.1°F. The wound was throughout dressed with 1 : 1,000 acriflavine solution.

31-7-26. Morning temperature 105°F. The intravenous injection of iodine was repeated at 1 p.m. The temperature at 5 p.m. was 102°F.

1-8-26. Temperature 99°F. in the morning. The same dose of iodine was given intravenously. Temperature 99.5°F in the evening.

2-8-26. Temperature 98.4°F in the morning and 99.5°F in the evening. It then fell to normal and remained normal; the patient being discharged from hospital cured two weeks later. He was soon on a meat diet, and was given tonics.

The daily injections, each of 1|2 grain of iodine in 40 minims of distilled water, appeared to have brought the fever under control very rapidly.

A CASE OF ACCIDENTAL ABDOMINAL INJURY.

By T. P. VARMA, M.B.,
Assistant Surgeon, Deoghar, Santhal Parganas.

ON the 25th April, 1926, at about 3 p.m., a Mahomedan male aged about 30 years, a labourer, was brought to the Deoghur Charitable Hospital with a wound about 2 inches long, situated horizontally on the left side of the abdomen, at the level of the umbilicus, from which some portion of the small intestine with the omentum was protruding.

While drawing water from a well supported on a wooden beam, the latter suddenly gave way, and the man fell down into the well, the above injury being caused by the broken beam. The man was brought into hospital with the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

coil of the intestine covered with a very dirty dry piece of cloth.

The patient was chloroformed and the gut was washed with warm saline and "E.C" lotion (1 drm. to the pint). Laparotomy was done as the gut could not be replaced through the wound. The coil and the mesentery were replaced and the wound stitched up.

On the 3rd May the stitches were removed and the injury and the laparotomy wound healed up by first intention, though the man had to be kept in hospital for the treatment of some other injuries. There was some rise of temperature for the first four days, the highest rise being to 103°F. From the fifth day the temperature continued to be about normal.

The special features of the case are the escaping of the gut uninjured, and the absence of any complication though the gut had been covered with a dirty piece of cloth.

I am grateful to the Civil Surgeon, Santhal Parganas, for kindly permitting me to publish the notes of this case.

A CASE OF BILATERAL DISLOCATION OF THE MANDIBLE.

By SATISH CHANDRA DAS, M.B.,
Mayo Hospital, Nagpur, C. P.

GANGARAM, Hindu male aged 26, a resident of a village about 28 miles from Nagpur, was brought to the surgical out-patient department of this hospital on the 25th October, 1926. His mouth was wide open, he had a parched expression, and was emaciated. His relatives stated that as the result of a violent fit of yawning five days before he could not close his mouth. I immediately wrapped a piece of gauze around each of my thumbs, put each on the cutting surface of the lower molar teeth on each side and pressed downwards, whilst the other fingers of each hand were directed towards the chin and exerted upward pressure. Within ten seconds the mandible rolled back into place in the mandibular fossa and the patient was immediately able to close his mouth. This method of reducing a dislocation at the temporo-mandibular fossa is, of course, a well known one.

The patient and his relatives were amazed at this immediate result, and the former prostrated himself as if in the presence of a diety in a temple. On further enquiry as to why the patient had not been brought for treatment sooner, the relatives said that at first, in accordance with the instructions of a local *vaidya*, external applications were applied. When these proved of no avail, they supposed that he was possessed by an evil spirit, and called in an *ojha* (ghost-exorcist) who made the patient undergo some rites and peculiar exercises, in spite of the fact that the poor fellow was by then practically starving. When *mantras* and the mysticism of the "specialists"—according to their own claims—could give no relief, and as the patient was getting more and more exhausted, they decided to try the local official civil hospital.

Cases such as this go a great way in creating confidence and regard, especially among village folk, in modern scientific medicine. This case also illustrates how much unfortunate patients sometimes have to suffer for the whims, hobbies and superstition of themselves and their friends, which may—and at times even do—cost them their lives.

A CASE OF SURGICAL EMPHYSEMA FOLLOWING FRACTURE OF THE 5TH AND 6TH RIBS.

By N. CHATTERJEE, M.B..
Domjore, Howrah District.

History.—An old man of 60 years, an habitual drunkard, had a merry evening. He went to the pond to wash himself, and slipped accidentally and fell on the pavement. He walked home a distance of three miles and I was called to see the patient next day for cough and hæmoptysis.

On examination I found the 5th and 6th ribs displaced inwardly, and the patient could not bear any pressure, however slight, on the ribs. Strapping being impossible at that stage, I wanted to displace the ribs outwards and asked him to submit to surgical interference, which he refused.

Treatment.—Calcium, opium and a purgative by the mouth. I kept him without any pillow.

I did not see the patient for five days and I was told that some evil spirit was working on him and this spirit had inflated his whole body and the man was unrecognisable, and many *mantras* were being chanted to drive out the evil spirit but with no effect. Preparations, were being made to carry him to the Ganges, as the quacks had declared him hopeless and pulseless. I hurried to the spot uncalled for and with greatest difficulty persuaded them to abandon the scheme of killing the man.

On examination, I found the heart normal, a few râles and some dullness at the base of the lungs, the pulse deceptive on account of the huge swelling of the hands. From the forehead to the toes the whole body was swollen and gave the characteristic crackling of surgical emphysema. The man looked double his former breadth and circumference. He was swallowing his food all right except for slight difficulty. At last I was given 8 hours' time to prove that he would not die. The daughter sided with me, and the party agreed to abandon their scheme for the time being. I wanted to make a few punctures, but the relatives refused to consent.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

I gave him a good strapping of adhesive plaster over the whole of the right lung, and a pad of cotton over it, firmly pressing against the fractured ribs. I gave him an injection of morphia for the cough. After cleaning the extremities I strapped the extremities with bandages and tried to prop the patient up in bed, but he could not bear this. I kept my compounder waiting there, and implored the daughter not to allow the patient to be taken away without my permission.

Next morning the quacks and the relatives saw me at my place and drew my attention to the fact that I was not allowing the old man to be taken away to the Ganges, and thereby going against Hindu customs and religion. They drew my attention to his drowsy conditions, which I explained them as the result of the morphia and asked for another 12 hours' time. To make a long history short, I managed with greatest difficulty to rid the patient of the most trusted "lieutenants of Lord Chitragupta of Jompore." I am glad to say that to-day the patient is perfectly fit and following his usual avocations.

A CASE OF ASCARIS INFECTION SIMULATING CHOLERA.

By Y. S. ROW, L.M.P.,

Markapur, Kurnool District.

EARLY in September 1926 I was called in to see a boy aged 12, suffering from diarrhœa and vomiting. At the time cholera was prevalent in the surrounding villages but not in the village in which the boy lived. I was told that the boy had passed 12 watery stools during the night, and had vomited 8 times. I found the patient in a state of collapse, his body cold and clammy, the pulse rapid and feeble, the tongue dry, with a tremendous thirst and cramps in the legs. In brief he suggested the clinical picture of cholera.

There had been no cases of cholera however in the village in which he lived. Without waiting to make a diagnosis, I gave him two pints of hypertonic saline solution with glucose and adrenalin intravenously. I also ordered 10 minims of liquor adrenalin hydrochloride to be dropped under the tongue every hour for six doses.

When I saw the patient six hours later, complete reaction had set in, his condition was much better, the pulse tension was moderate. I was told that he had had four watery stools and had vomited three times since I had seen him before; also the important fact was elicited that when he had last vomited he had brought up a round worm. I now suspected that the condition might be due to Ascaris infection, since the symptoms due to this infection are often very severe and of very varied character. I immediately gave a full dose of santonin—grs. 5—the same day. By the next morning, without any additional purgative, the boy had passed 43 round worms, and continued to pass round worms both orally and *per rectum* for the next week,—the total number passed being 164 worms.

A second dose of santonin was given on the fourth day in order to finally eradicate the infection and the patient made an uneventful recovery.

The case is of interest as shewing the very severe symptoms to which Ascaris infection may give rise.

THREE INTERESTING CASES OF MALIGNANT DISEASE.

By J. B. VAIDYA,

MAJOR, I.M.S.,

District Medical Officer, Kurnool.

Case 1. An Extensive Carcinoma involving the Transverse Colon.

A HINDU male aged about 30 was admitted for ascites of six months' duration.

The patient was wasted and anæmic. The abdomen was very tense and distended, with prominent veins on the surface. There was an enlarged gland in front on the right side of the chest about one inch below the right nipple. The liver and spleen could not be felt. The abdomen was tapped and about 5 pints of reddish fluid came out. With the abdomen lax one could feel hard masses in the abdomen. One mass was felt lying transversely at the level of the umbilicus and two more were found in the lower part of the abdomen. An exploratory laparotomy was carried out. The great omentum as such could not be seen. It was rolled up into a mass in the growth. The splenic flexure of the colon and the transverse colon were involved in the growth which was hard and nodular. Growths were also found in the mesentery and the mesenteric glands. There were secondary carcinomatous deposits in the liver. The stomach and the duodenum did not show any malignant growths. The man lived for a few days but died of exhaustion and shock. A post-mortem could not be obtained.

Case 2. A Case of Carcinoma of the Pancreas.

A man aged about 50 was admitted for pain in the region of the stomach and gradual wasting. The man had worked as a coal miner in South Africa. There was no history of syphilis, or of jaundice.

On examining the abdomen a hard nodular mass was felt, about an inch above and to the right of the umbilicus. The abdomen was sunken and the supraclavicular glands were enlarged on the right side.

There was no vomiting and the appetite was fairly good. There was no albumin or sugar

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in the urine. The man was advised operation for gastric carcinoma, but refused. The patient was kept in hospital for three months, during which time the pain increased in severity but there was no vomiting. There was great emaciation. The patient gradually got weaker and weaker and died. A partial post-mortem was done and on opening the abdomen, the stomach and the pylorus, and the duodenum did not show any growth; but the pancreas was enlarged, hard, and adherent to the posterior abdominal wall.

Pathological report.—Adeno-carcinoma of the pancreas.

Case 3. Sarcoma of the Breast.

A woman aged about 35 was admitted for a tumour, the size of a mango, in the right breast. She gave a history of an operation done three years previously for a tumour in the right breast. The records showed that a fibro-adenoma was removed from the breast. The tumour was freely movable on the subjacent tissues and felt hard and globular. The skin was not adherent to it. There were no enlarged glands. The tumour was thought to be carcinomatous and was removed along with the pectoralis major muscle. On removal the tumour was found to have a capsule, and a few cavities in which proliferating masses were seen in one part of the tumour. The pathological report on the tumour was that it was a spindle-celled sarcoma. The case is thought worth recording as sarcoma of the breast is believed to be rare. Sampson Handley however, says that "the routine histological examination of tumours of the breast has shown that sarcoma of the breast is much more frequent than it was formerly thought to be."

A CASE OF IMPERFORATE HYMEN.

By P. BHASKARA RAU,
Medical Officer, Local Fund Hospital, Narasapatam.

R. P., a girl aged 14 of the agricultural class, was brought to me on the 6th April, 1926, for relief of retention of urine. She gave a history of difficulty in micturition for the past fortnight, with great pain during defæcation; and for the last three days had had complete constipation and retention with overflow of urine.

When she was being prepared for catheterisation, a condition of completely imperforate hymen was discovered. Enquiry elicited the fact that she was married, but that her husband was in Rangoon and that the marriage had not yet been consummated. She had attained puberty six months previously, but had never menstruated. Her mother-in-law threw out dark hints that the girl was about to become a mother before ever she was a wife, but this slander the patient indignantly repudiated. Hence her relatives had brought her for medical opinion.

At operation no vaginal orifice could be discovered, whilst there was a bulging mass between the labia, covered by a thick and glistening membrane. The external urethral orifice was drawn up, whilst the anus was everted and the anal condition resembled a severe case of hæmorrhoids. A catheter was passed with difficulty and about 30 ozs. of urine was drawn off. The bowels were relieved by enemas, and operation performed the next day under a general anæsthetic. I first stabbed the tumour with an exploring needle (to confirm the diagnosis, since the medical man in the *mofussil* cannot afford to make mistakes), when a few drops of thick dark blood escaped. An incision was then made through the lower part of the membrane, when 22 ozs. of thick, dark, and offensive blood-stained fluid escaped. The vagina was opened out and douched with hot lysol lotion, and then packed with lysol gauze. For a few days a thick rubber tube was kept in the incision in order to keep the orifice patent. At operation the uterus was found high and drawn up, but otherwise normal. The patient made an uneventful recovery and was discharged cured a week after operation.

I wish to thank Dr. N. Venkataswami Chetti, District Medical Officer, for kindly permitting me to publish the notes on this case.

A CASE OF LARGE OVARIAN CYST IN A YOUNG WOMAN.

By M. K. PILLAI, B.A., M.B., C.M.,
Civil Surgeon, Pegu, Burma.

THE patient, a Burmese woman, aged about 22 years, married but with no children, was admitted to hospital with an enormous abdominal tumour of about one and a half years' duration. The tumour occupied the entire abdominal cavity, extending above to the costal arch, pushing the spleen and liver before it, below to the symphysis pubis, and to Poupart's ligaments on both sides, and backwards to the erector spinæ. It was tense and fluctuating on the right side, and hard on the left side. The patient had been married a year before admission and stated that at that time the tumour was in the left iliac region and about the size of a walnut. The menses were regular but scanty. Her temperature and pulse were normal but she was rather anæmic and subject to asthmatic trouble, probably due to the mechanical pressure from below of the tumour, whilst the urine shewed a trace (only) of albumin.

After a week's treatment with tonics and mild laxatives, operation was performed under chloroform anæsthesia. The tumour proved

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

to be an ovarian one, and about 20 lbs. of a brownish-white gelatinous fluid were evacuated on tapping it with a trocar. It was a large multilocular cyst of the left ovary, whilst the right ovary was also found to be cystic and about the size of a small walnut, and was therefore, also removed. The patient made an uninterrupted recovery, except for some dragging pains in the abdomen on the second and third days after operation—in all probability due to the displaced abdominal viscera resuming their normal locations. She was discharged quite hale and well from hospital after a fortnight's stay, and with an abdominal support.

The interesting features of the case are—

(1) The very large size of the cyst in so young a woman, and

(2) The rapidity of the growth.

The patient has since been seen three months after operation, and was apparently quite fit, but had had no return of the menses.

A CASE OF PAROVARIAN CYST.

By Rai Sahib CHHAGAN NATH,

Chief Medical Officer, Dungarpur, Rajputana.

A HINDU woman, aged 40, a primipara, came to the Bijey Hospital, Dungarpur, stating that she had suffered for ten years from a growth in her abdomen. She added that the growth was at first felt on the left side but had gradually grown until it ultimately filled the abdominal cavity. On examination externally and

per vaginam, the tumour was discovered to have burrowed deeply into the pelvic cavity, chiefly to the left of the uterus.

Operation.—The abdominal wall and peritoneum were incised over the prominence of the tumour at a site as little vascular as possible, and the hand inserted. A few minor adhesions were found and broken down. The cyst was then tapped and yielded 19 pints of clear, limpid fluid. The layers of the broad ligament were divided in front and at the back, and the tumour was finally delivered by blunt dissection, with occasional snipping by the scissors. The bed of the tumour was then sponged dry, the broad ligament incisions sutured, the peritoneal toilet made, and the abdominal wound closed. The wound healed by first intention, and the patient was discharged cured in three weeks.

The photograph shews the patient before operation.

A CASE TYPICAL OF RURAL MIDWIFERY PRACTICE.

By C. G. DHANDHUKIA,

Medical Officer in-charge Jesar Dispensary, Bhavnagar State, Kathiawar.

THE following case presents many points of interest and is in itself a reply to the last paragraph of Dr. Jhaveri's article "An interesting case of transverse presentation" in the *Indian Medical Gazette* for December 1925.

A farmer's wife, well-built and of healthy physique, aged about 17 years, was seen by me in labour at 10 p.m. on the 19th July 1926 at her house in an adjoining village in response to a hurried and urgent call. Her history was that she had completed full term, had had no illness during pregnancy, and that she had commenced to feel weak pains thirty-two hours previously. Her abdomen had been massaged by friends and two hours later a fœtal hand prolapsed and appeared. Her female attendants subsequently tried lubrication with *ghee*, traction, friction and massage with a view to delivery, but were unsuccessful.

She was a primipara and the pulse of good tension. The pains, however, were irregular and ineffectual and the fœtal heart sounds absent. The right upper fœtal extremity was protruding through the genitals and was swollen, black in colour, with no pulsation anywhere in the protruding fœtal limb. The limb was covered with *ghee*, as also were the maternal parts. Digital examination shewed that the cervix had contracted on the protruding parts, all amniotic fluid had been lost, the fœtus was jammed in the pelvis, and the condition present was one of dry, difficult, and obstructed labour. Hospital conveniences, assistants, chloroform, etc., were not available, the cottage conditions were the worst possible, with a very poor light, no

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Barnes or de Ribes' bags or other hydrostatic dilators were to hand.

Having nothing else available, I thought of giving chloral, and at once gave 10 grains of chloral hydrate in solution. The same dose was repeated an hour later, but relaxation of the parts did not occur. The patient by degrees became drowsy between the pains, and manual dilatation of the vagina—which in this primiparous patient was rather narrow—was gently commenced. The uterus still remained firmly contracted on the fœtal parts. As the fœtus was undoubtedly dead, the protruding limb was cut off, and not a drop of blood escaped. By combined gradual internal and external manipulation the fœtus was turned, and a breech presentation secured. Shortly afterwards a full term, dead male fœtus was delivered by natural efforts without further trouble, and the placenta came away by natural expulsion. The patient made an uneventful and complete recovery and is today in good health.

The case is remarkable for the entire absence of puerperal sepsis in spite of (*1*) premature rupture of the membranes and the meddlesome midwifery of ignorant female attendants; (*2*) the many hours of obstructed and protracted labour; (*3*) death of the fœtus; (*4*) the damp septic atmosphere of the monsoon with a feeble illumination, no assistance, and a complete absence of all ordinary facilities; and (5) manual interference with the delivery. I have purposely used the word *ghee* instead of its English rendering boiled butter, lest it be understood that it was butter recently boiled and therefore sterile. This was not the case. I have since used chloral hydrate in other cases in my practice and have come to the conclusion that the drug is of special value under such difficult circumstances.

In all probability the transverse presentation in this case was due to the massage carried out by untrained hands at the commencement of labour—a practice which is very common in India. The qualified—and especially male—practitioner in India is only called in when an impasse is reached; and the whole case is typical of midwifery under rural and *mofussil* conditions in India.

TWO INTERESTING CASES OF MALARIA.

By SATYA KINKOR BISWAS, L.M.,

Medical Officer, Kirkind, Kusunda P. O., Jherria Coal Field.

Case 1.—I was treating a patient suffering from what appeared to be cerebral malaria at Bansjora, E. I. Ry., when, during one of my visits, the brother of the patient was shewn to me as he was suffering from slight fever, his temperature being 100°F. Except for slight fever and a coated tongue I could find nothing wrong with him and I prescribed fractional doses of calomel, to be followed by sodium sulphate, and left the house at about 11 a.m.

Two hours later a man came in a taxi to inform me that the second patient—a young lad aged about 18—had suddenly become delirious and unconscious and was lying in this state on his bed. I went to see him at once and found him unconscious, with the tongue protruding, saliva trickling from his lips, a temperature of (only) 101°F, pulse 105 and feeble, respiration rate 30 per minute. His heart, lungs and reflexes were normal.

As I could not find out what was the matter with the patient, I prescribed liquor adrenalin hydrochloride, 1 : 1,000 solution; m. 5 every 4 hours for 3 doses, and cold application to the head. Four hours later I again visited the patient and found him in practically the same condition. In view of the fact that his brother was suffering from cerebral malaria, I gave him an intramuscular injection of 5 grs. of quinine. The following morning I found him much better, and subsequent intramuscular and oral administration of quinine cleared up all his symptoms.

Sudden unconsciousness with a relatively low temperature must surely be uncommon in cases of malaria.

Case 2.—I was called in to a colliery to see a child aged 3½ years old suffering from convulsions. The history given was one of chill and slight fever for the previous 2 days, with the onset of convulsive fits that morning, the fits growing steadily more and more frequent and intense. The child had only come to the colliery 6 days previously from a severely infected malarious village where his relatives were suffering from malaria.

On examination I found the temperature to be 99.8°F, the pulse of good tension, slight rhonchi in the lungs, the heart and abdomen normal. The breathing however was sterterous and jerky, tending towards a choking condition at the time of the fits, with the limbs rigid during the fits. I called in Colonel Price, I.M.S., in consulation, but we could give no definite diagnosis, and castor oil and chloral and bromides were prescribed for the night. In the morning I found the patient with a temperature of 104°F, and considering the history of malarial attacks in the household where he had lived, I gave an intramuscular injection of 2½ grains of quinine, with 1½ grs. t.d.s. by the mouth. The patient made an uneventful recovery. Later on, I learnt that blood films taken from the patient at the time when he was seen in consultation had shewn the presence of the parasites of benign tertian malaria.

PHARMASOLS

REGD.

THE MOST EFFICIENT COLLOIDS

Truly scientific, active, reliable, economical, stable, Colloidal preparations of standard drugs for medicinal use.

Pharmasols REGD

CALCIUM

The one line of endeavour in the treatment of **TUBERCULOSIS.**

Pharmasols REGD

SULPHUR

A well-known specific in Subacute and Chronic Rheumatic Affections.

Pharmasols REGD

IODINE

The ideal form of Iodine treatment in Pneumonias, Influenza Plague, etc.

Pharmasols REGD

TRIMINE

Remarkably useful in Eczemas and Obstinate Skin Diseases.

Pharmasols REGD

MANGANESE

May safely be termed a true specific in all Staphylococcic and Streptococcic infections and its field of usefulness is therefore very extensive.

Pharmasols REGD

FERRO-MALT CO.

Is of unquestionable value in Anæmias, Rickets and Rundown Conditions.

Don't use other Colloids until you have seen and tried Pharmasols. They are recognized as being completely in advance of everything else in the Colloidal line and these new improved Pharmasols are without a rival in quality and low prices to-day. The word Pharmasols is your guarantee that these Colloids are of immense popularity throughout India, Burma and Ceylon, unsurpassed for reliability, economy, and stability, because the methods of manufacture of these Colloids are totally different from all other so-called Colloidal preparations offered for sale in this country. Those Doctors use them who most seriously want low prices and guaranteed results. Always insist on Pharmasols.

DOCTORS

Beware of Dangerous and Fraudulent Imitations.

Read this carefully. *Times of India.*

SKILFUL IMITATION OF PRODUCTS.

FRAUD ON CHEMICAL FIRMS.

Special to "Times of India."

PARIS, (By Mail).

So cleverly did a gang of fraudulent patents medicine vendors make up and sell quantities of faked medicines to chemists in Paris and elsewhere in France that the proprietors of the patent medicines themselves when asked by the police were unable to distinguish their own products from the faked ones. The bottles, labels, printing and wrappings were all exactly imitated. Large shipments were made to Cuba and Mexico by deluded purchasers of the counterfeit medicines. Several arrests have been made but the police do not yet believe that they have caught all the men involved in the fraud which has cost reputable houses many thousands of pounds.

One of the cheated chemists with the connivance of the police set up a temporary export bureau and gave an order to the suspected persons. They duly delivered the falsified goods only to find themselves on arrival in the hands of the police.—British United Press.

SULFARSENOL AND

ONLY GENUINE PACKING

FOR INDIA

Imitations of SULFARSENOL of inferior quality have been put on the market by unscrupulous and cheap firms.

Beware—These fraudulent substitutes are no good for India. They do not keep fresh, they loose their activity and become dangerous toxic drugs.

For a few annas it may be a question of LIFE or DEATH for your patient. YOU may lose YOUR REPUTATION and PRESTIGE.

Insist on the only Genuine Package—it is in your own interest.

Note the only Genuine Package of

SULFARSENOL

Specially prepared for India and carrying the FULL GUARANTEE OF THE MANUFACTURERS.

If your chemist cannot supply the genuine SULFARSENOL, write to the

INDO-FRENCH DRUG Co.,

P. O. Box 458, BOMBAY.

Warning.

Genuine SULFARSENOL in the genuine packing is the only product passed by the Medical Research Committee and no other will be replaced in case of complaint.

BENZO-BISMUTH A.F.D.

THE ONLY ONE SOLUBLE, STABLE, NON-TOXIC BISMUTHIC ORGANIC SALT, OF HIGH SPIROCHÆTICIDAL POWER THAT DOES NOT CAUSE BISMUTHIC POISONING WHICH ADMINISTERED BY INTRAMUSCULAR INJECTION IS PAINLESS AND IN MANY RESPECTS SUPERIOR AND CHEAPER TO OTHER BISMUTHIC PREPARATIONS USED IN THE CURE OF SYPHILIS.

MAIN ADVANTAGES

(1) The small quantity that is injected, not exceeding 1·5 c.c.
(2) The ease with which the drug is administered either intramuscularly or subcutaneously.
(3) The painlessness after injection.
(4) The uniformity of dosage.
(5) The comparative cheapness.
(6) No liability to toxic symptoms.
(7) Complete solubility of the drug in a watery medium without leaving any particles in suspension.

In Benzo-Bismuth A.F.D the Physician has an extremely active weapon, easily handled, without danger, without risks and with the minimum of inconveniences, capable of giving results as marvellous as those previously obtained only with arsenic.

(Presented in box of 5 ampoules of Benzo-Bismuth A.F.D.)
(Accompanied by 5 tubes of Distilled Water.)

QUINARSINE A.F.D.

A very active specific against Malaria, and a regular treatment which will result in the cure of the disease, and the rapid disappearance of gametes from the blood.

In ampoules and pills.

BLENACROL A.F.D.

A very powerful Antiseptic, non-caustic, non-toxic, for urethral injections in the treatment of GONORRHOEA and its complications.

In bottles containing about 3 ozs.

FEBRUARY.

NEW LIGHT ON THE EPIDEMIOLOGY OF CHOLERA.

SIR LEONARD ROGERS has spent twelve months of intensive work on the epidemiology of cholera. The record of his labours is published in the *Proceedings of the Royal Society of Medicine* for 1926 (Vol. XIX). Sir Leonard was struck by the fact that there was still much to learn about the incidence and spread of cholera over India. Spread of infection by human travel is by no means the sole factor, the disease spread just as rapidly in 1817-18 as it did in 1859-71. Even now the sequence of events is much the same as it used to be in spite of the great increase in the speed of travel. In 1869 Bryden showed that the Punjab epidemics coincided with the spread of the south-west monsoon, and so originated the view that the disease was spread by the wind. The spread of the disease does not follow the lines of railway travel.

Remarkably accurate information exists about the 1817-19 epidemic, which was recorded by Jameson. In August and September 1817, the disease was epidemic over most of Bengal and in November it attacked Hasting's Army in the south-east of the United Provinces. As usual, it died down in the cold weather but in March 1818 it appeared at Allahabad and Banda, and spread all over the United Provinces in April and May, reaching the Punjab in the rainy season July to September. From the north of the Central Provinces which were affected in April it spread due south, reaching Hyderabad in July, and thence east to the coastal districts of Madras and to the south of Madras province, which was infected in August and September. From the north of the Central Provinces another wave spread west and south-west, reaching Bombay in August. This terrible epidemic travelled in much the same way as most of the subsequent outbreaks up till 1870, which followed the same routes in spite of the opening up of railways.

Bryden in 1870 after a careful study of several epidemics reached the conclusion that cholera is "dependent on an atmosphere of moisture for epidemic invasion."

Rogers, independently, reached the same conclusion before he had read Bryden's work, but he differs from Bryden's view that the spread is by moisture-laden wind. Rogers finds no evidence of *regular* cycles such as were described by Major Russell and several of his predecessors, and agrees with Cornish that epidemics occur at irregular intervals dependent on factors which he (Rogers) has worked out.

It is interesting to note that Andrew Duncan's career in India was ruined because he dared to write a paper opposing Cunningham's wind-borne theory of the spread of the disease and his belief in the non-infectious nature of cholera. At this time (1884), the Government of India actually forbade its servants to publish views suggesting the spread of the disease by human intercourse. Rogers finds that the relationship between cholera epidemicity with air temperature and relative humidity is inconstant, but when he examined the records he found that when absolute humidity is below 0.400 during the cold weather, cholera falls to a very low rate or disappears altogether. In Assam and Lower Bengal, the winter decline of the disease follows shortly after the period of lowest absolute humidity. The absolute humidity is an index of the combined temperature and moisture of the air and so may well affect the extra-corporeal life of the vibrio.

In all places which show a high average cold weather rate for cholera the absolute humidity is over 0.400, while in all areas which have a low average cold weather rate the absolute humidity is below 0.400.

Rogers believes that the atmospheric condition which favours cholera epidemic is high absolute humidity of the air.

The important question of endemic areas is discussed. Lower Bengal, Orissa and Assam constitute a hyper-endemic cholera area, the lowest annual rate never falling below one-tenth of the average rate for thirty years; in this area the absolute humidity never falls below 0.400. There are three other areas in which cholera has never been completely absent for one year during thirty years; these are—

(1) Behar, Chota Nagpur and part of the United Provinces.

(2) The low-lying districts of south-east Madras.

(3) A small low-lying strip of the North Konkan districts of Bombay.

All of these areas show an absolute humidity of over 0.400 throughout the year.

Rogers does not agree with the popular view that Lower Bengal is the one great home of cholera from which epidemics spread over the whole of India. He agrees that the 1817-19 epidemic spread from Bengal and that several others have also originated in that province, but he shows that exacerbations of the disease have been more frequent in some areas which are far distant from Bengal than in others which are nearer. He therefore inclines strongly to the view that there are other endemic areas besides Bengal. Jhansi, for example, showed eighteen epidemics in thirty years, having been invaded not only from the adjoining divisions in the United

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Provinces but also from the Central Provinces. The great outbreak of 1875-77 illustrates this point, it appears to have originated in three distinct endemic areas—

(1) In the eastern sub-Himalayan divisions of the United Provinces in February and March 1875.

(2) In Nasik near Bombay in March 1875.

(3) From Tanjore in Madras in April 1875.

Pilgrim movements played a great part in spreading this devastating epidemic.

An important factor in predisposing to this outbreak was the previous prolonged deficiency of rainfall and the resultant famine conditions. In nearly all the other epidemics which have been studied, there was also a previous long spell of deficient rainfall. Several examples are given to show the well known importance of pilgrim gatherings in spreading the disease. The important factors in the spread of cholera thus appear to be

(1) High absolute air humidity.

(2) Preceding deficient rainfall.

(3) The introduction of infection, especially by returning pilgrims.

Rogers believes that it is possible to predict an epidemic and to prevent it by the compulsory inoculation of pilgrims as well as by the other sanitary precautions which are at our disposal to prevent pilgrim gatherings from being "cholera exchanges."

Altogether this paper is one of outstanding importance, it is worthy of closest and most critical study by all who are engaged in the work of cholera prevention. Some of the points which require further investigation are (1) Granted that high absolute humidity of the air is essential to the development of an epidemic, how does this affect the extra-corporeal life of the bacillus? If the organism is water-borne the air conditions would not be likely to influence the life of the vibrio. If flies and hand contamination play the most important parts in the spread of the disease, atmospheric conditions might well influence the sustained life and virulence of the vibrio outside the body and it ought to be possible to carry out experiments on this point. In these, natural conditions should be simulated as closely as possible. (2) Rogers strongly hints at individual susceptibility as being an important factor; he refers to the complete absence of the disease for a previous period as preparing the population for an outbreak, and he indicates that a great epidemic is followed by a period of mass immunity. (3) Another point of importance is whether climatic conditions affect the individual resistance to infection in the same way as happens in the case of infection by *Entamœba histolytica*.

It is to be hoped that Sir Leonard will be able to continue his important studies and to include a comparative analysis of outbreaks which occur in cold climates. The whole subject is highly complicated and difficult. This paper is not the last word, but it is a very weighty one.

IS EPIDEMIC DROPSY AN INFECTIOUS DISEASE?

THE very interesting paper by Dr. Anderson in this month's issue brings into prominence the question of infection in epidemic dropsy. Any disease in which individuals belonging to closely associated groups of people are attacked in rapid succession is naturally regarded as being likely to be communicated from person to person and so it becomes necessary to investigate rather closely the conditions under which the disease occurs. Epidemic dropsy shows a striking tendency to affect a number of people who are closely associated with each other and for some years it was almost universally accepted as being a communicable disease. Evidence gradually accumulated which resulted in a complete change of opinion on this point and there is now a very large volume of evidence which goes to show that ordinarily the disease is not communicated from person to person, but affects a number of persons who are exposed to some common influence. Dr. Anderson states the facts which have come under his observation in a clear and judicial manner and it is likely that the majority of our readers will be convinced of the truth of his conclusions with regard to the Kalna outbreak.

The Kalna outbreak was peculiar in two respects, the first and most important being that it occurred soon after the arrival in Kalna of persons suffering from the disease. There had been no epidemic dropsy in Kalna previously and the disease affected none but those who were in close contact with patients. It is true that there were cases of epidemic dropsy at Nawadip which is a few miles away from Kalna; these occurred about the same time as the Kalna outbreak so that Kalna must be regarded as being within the endemic area of the disease. It would, however, be a very remarkable coincidence that the very people who came into contact with the imported patients should be the ones to be attacked and it is much more likely that there was a true association between the outbreak and the importation of the disease. There are only two likely explanations.

(1) That person to person communication of the disease actually occurred: if so, this is a very remarkable occurrence and one which is contrary to the usual experience that the affected persons who go to a non-endemic area do not convey the disease to others.

If infection actually occurred as is suggested by the reported facts, we must regard infection as being a possibility in spite of its rarity.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(2) That the imported patients brought a supply of rice with them and shared it with their personal friends, who thus became attacked. If this had happened, it is hardly likely that it would have escaped the observation of Dr. Anderson who made very careful enquiries into the circumstances connected with the outbreak.

It is interesting to note that the Kalna outbreak was of the usual explosive type, twelve out of the eighteen patients being attacked within eight days and all the fresh cases within less than six weeks. All the fresh cases occurred among people who obtained their rice from one shop, but many others who also bought rice from the same shop escaped. Dr. Anderson failed to find evidence that one sample of rice could be responsible, and altogether his record is rather strongly in favour of the possibility of a poison being produced in the intestinal tract of persons who became infected with a special organism. This is a possibility which we have always kept under consideration, but all the observed facts in connection with many observed and recorded outbreaks are opposed to the view that this is a common occurrence. It is only by the accumulation of such observations as those made by Dr. Anderson that a true understanding of the causation of the disease can be reached. Meanwhile the broad facts remain as before, the disease as a whole is best explained as a rice intoxication, and while it is quite possible that in exceptional cases the poison may be formed by microbic action on the intestinal contents, it is more usual for the poison to be pre-formed. In any case the rule that rice should be cut out of the diet is the proper one to follow and there is abundant evidence to show that any outbreak can be controlled by withholding rice.

Dr. Anderson's paper is a valuable contribution to the subject and the evidence produced by him must be carefully weighed by anyone who wishes to arrive at the truth regarding epidemic dropsy.

The clinical manifestations were those of a fairly mild outbreak.

SPECIAL ARTICLES.

GYNÆCOLOGY AND OBSTETRICS: A PRACTICAL SURVEY OF RECENT AUTHORITATIVE OPINIONS.

By V. B. GREEN-ARMYTAGE, M.D., M.R.C.P. (Lond.),
LIEUT.-COLONEL, I.M.S.,
Professor of Gynæcology and Obstetrics, Medical College, Calcutta, and Surgeon to the Eden Hospital.

Sterility, or the inability to conceive, is relatively common in human beings, as compared with lower animals, and it would seem that with the ever-increasing lateness of marriage the reproduction rate must fall, due to causes in the woman or the man.

One of the greatest advances in gynæcology in recent times has been the introduction of the Rubin method of testing the patency of the Fallopian tubes in those cases where the explanation of sterility hitherto was unrecognisable. If there is a block in the canal from the uterus to the fimbria on three separate occasions, with the uterus in the normal position, operative procedure is not likely to benefit the patient. If the uterus is retroverted and symptomless and the tubes are patent no operation is indicated, but if the tubes are only patent after first anteverting the uterus, the probabilities are that the retroversion is causing a mechanical kink. Then a modified Gilliam or Williamson operation is advisable.

Complications of Pregnancies.

Heart Disease.—It must be remembered that many cardiac patients do not show any symptoms until after labour.

Out of 38 cases of heart failure after labour, 5 died in hospital during the puerperium, and 8 more died within the year; 6 with mitral stenosis died immediately after labour. Myocarditis is the worst complication of all. It must be realised that disturbances in heart function are not due to mechanical factors, for 40 per cent. occur during the first three months of pregnancy. The fault lies in the increased demand on the heart muscle made by the increased blood volume. No hesitation should be felt in inducing labour if there are indications that the heart is going to fail. If failure has occurred, no interference with the uterus is permissible.

Tuberculosis.—Much discussion has occurred on this subject. Some are absolutely against terminating pregnancy, others are for doing so. The middle and the wisest path would appear to be that if there are active signs of the disease, and the patient is under fifteen weeks pregnant, the uterus should be evacuated. The most important point is often overlooked, namely—the future of children born of tubercular mothers, for it has been proved by careful statistics in England and France, that more than 40 per cent. of such infants die within the first year of life, even where segregation has been compulsory. This being the case, it is not difficult to understand the enormous infantile mortality in the large cities of India, where education and the benefits of segregation have not as yet penetrated.

Pernicious Anæmia of Pregnancy.—The problem of this disease, rare in the West, and exceedingly common in India, still remains unsolved. It is most often encountered in multiparæ, and may date back to the very beginning of gestation. At times there is diarrhœa, in most patients there is some fever and slight albuminuria; epistaxis, and retinal

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

hæmorrhages are common. It is thought that the various lipoids found in the blood of pregnant women are a causative factor. There are four possible terminations—(*a*) death during labour (which is premature in 90 per cent. of the cases); (*b*) death a few hours or days after delivery; (*c*) death weeks or months later; (*d*) very rarely, a rapid cure after delivery, with a return of the blood picture to normal.

The treatment of choice is direct blood transfusion, and early evacuation by tents in the early months of pregnancy. *X*-rays to kill the fœtus have been employed in recent years, and then the gestation is left to nature to abort.

An interesting point is that the blood of the infant, if born alive, is quite normal.

Post-Maturity.—The dangers of this condition have been stressed again and again. Ten days after the full term date is the maximum period beyond which it is unwise to wait for the onset of labour. Provided there is no disparity between the fœtal head and pelvis, medicinal induction of labour is first indicated. The castor oil-quinine technique for induction is successful in over 70 per cent. of cases, and is particularly useful in cases of accidental hæmorrhage, and marginal or lateral placenta prævia, for many of these cases when first seen are in a condition of temporary comfort, following a smart hæmorrhage, or exhibit a constant slight loss, which continues for some time. Here the uterus is contracting irregularly and at long intervals, or not at all, and there is little or no dilatation of the os. The castor oil-quinine technique, with or without the additional use of pituitrin, is attended with such success in these cases, as to negative to a large degree, any other interference, thereby decreasing the risk of sepsis. In post-mature or other cases, where the medicinal method of induction fails, if bougies or the stomach tube be introduced within twelve hours of the last dose of quinine, strong labour pains commence.

During the last year many articles have appeared urging induction of labour rather than Cæsarian section in those borderland cases of disparity, when either the pelvis is on the small side, or the baby big, because the risks of induction in properly chosen cases are infinitesimal. The whole question resolves itself into the proper application of ante-natal care, for the incidence of fœtal death and maternal morbidity would be very greatly reduced if every pregnant woman was examined conscientiously in her 37th week. If there is definite overlapping Cæsarian section obviously is indicated, but if the head can engage and the outlet is normal, in a primipara or one who has had previous difficult labour, a frank explanation of the advantages of induction and its negligible risks to the mother is undoubtedly the wisest course. However, it is well that the practitioner should remember that there is considerable danger attending the use of forceps in delivering premature infants, especially in posterior positions.

Non-Dilatation of the Os is one of the commonest causes of anxiety in labour, but if the membranes are intact, beyond the weariness of waiting, there is no need for anxiety, either as regards the mother or the child. But it is a very different matter if the membranes have ruptured, for in the writer's experience, if the pelvis is normal, in the great majority of cases this spells a posterior position, that is non-flexion, non-rotation, and therefore inability to descend.

These cases of non-dilatation of the os are common, and among the most difficult ever met with. What is best treatment? The rectum should be emptied, and hot vaginal douches given every four hours. First try morphia $\frac{1}{4}$ gr. and 1|100th gr. scopolamine, and repeat with 1|400th gr. of the latter every hour for three doses. If there is no progress, give 25 grs. of chloral and 40 grs. bromide, repeating in four hours.

If the labour has already lasted two or three days, or the above methods fail, you must bear in mind that the woman is in a state of exhaustion, the chances of delivering a live baby are practically nil, and that the case will become septic. Therefore it is best to perforate the head and allow the brain matter to escape. A cranioclast is then applied to the head and a weight of 4 lbs. is attached to the handle of the cranioclast, and made to hang over the end of the bed. The patient is now left alone. In the course of a few hours the cervix will dilate and the baby be born. The advantages of this method are that the risk of post-partum hæmorrhage is minimised, and there is no tearing of the cervix or perineum.

Intracranial Birth Injuries.—It is now generally recognised that cranial stress depends on two main features:—(1) The outside pressure to which the fœtal head is subjected. (2) The degree of congestion of the cerebral veins and sinuses. Post-mortem evidences of cranial stress are tears of the tentorium, marked engorgement of the vessels of the pia mater, choroid plexus and great sinuses, with or without intracranial hæmorrhages. It is suggested that tears of the tentorium are a sign not so much of undue force exerted upon the head but that this force has been exerted in the wrong diameter, viz., the occipito-frontal: intracranial hæmorrhages are due to intense venous congestion or the stress of delivery. It has been noted that when forceps have been applied to the fully flexed head, the damage and death incidence is greatly reduced.

Ante-Partum Accidental Hæmorrhage.—Fitz-Gibbon, from the statistics of the Rotunda Hospital, observes that this condition is much

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

more common in multiparæ than primiparæ; for instance, out of 115 cases 99 were multiparæ and 16 primiparæ. Considering the fact that *ante-partum* hæmorrhage is nowadays generally conceded to be of toxæmic origin, it is remarkable that the severest type of toxæmia, namely eclampsia, is far more frequently seen in primiparæ. Therefore it must be assumed that the type of toxæmia is different in each case.

He considers there are two types of *ante-partum* accidental hæmorrhage totally unconnected, one a simple and truly accidental ablation of part of the uterine wall, involving the placental site, in common with the rest of the uterus.

In this type it may be that there is low implantation of the placenta, but as the placenta cannot be reached these cases are not diagnosed as placenta prævia. The only symptom is external bleeding, the fœtus is not affected, and the mother remains well. These cases can be terminated by any of the recognised slow methods of induction of labour. In another variety of this type, due to injury or fall, or traction on the cord, there may be bleeding between the placenta and the uterus, with clotting of the blood, and the extrusion of sanious serum from the cervix. The urine is free from albumin, and the fœtus may be born alive and healthy, according to the extent of the hæmorrhage and the time of onset of labour.

In the second or toxæmic variety, these are all multiparæ, and all have albuminuria, for the mother is suffering from chronic interstitial nephritis. Recurrence of pregnancy throws a culminating strain on the kidneys, and results in a subacute exacerbation of the nephritis. There is degeneration of the connective tissue between the muscle fibres, and a extravasation of blood into this tissue between the muscle fibres and an oozing of blood into the cavity of the uterus. The degeneration occurs all over the uterus, under the peritoneum, and in the decidua.

In such patients the commonest symptom is a sudden gush of external bleeding which is dark red in colour, the urine is scanty and albuminous and the patient obviously very ill. The fœtus as a rule is dead.

Fitz-Gibbon demonstrates very clearly from his own results and the published reports of other hospitals that the accepted teaching of plugging the vagina or Cæsarian section for these severe toxæmic patients with apoplectic uteri is erroneous, and based on a wrong appreciation of the pathology of the disease. He advocates that those patients that are in labour should be allowed to complete delivery without interference, but if the uterus is tense or painful or the patient in profound collapse, only puncture of the membranes should be performed. The patient should be kept warm, and saline 9 ozs., glucose 1 oz. given three hourly, per rectum. Water by the mouth is given freely, and if need be, 10 to 20 ozs. of saline with bi-carbonate of soda injected into the vein. Pituitrin before delivery has little effect, but given immediately after delivery it is useful in order to anticipate possible *post-partum* hæmorrhage. The placenta is usually followed by masses of old hard black clot, demonstrating the origin of the disease. He states that operative interference, e.g., version, plugging, Cæsarian section, have hitherto been the direct causes of the enormous mortality, whereas the adoption of the above treatment of masterly inactivity has reduced the mortality to under 15 per cent. during the last five years at the Rotunda Hospital, a very striking testimony to the correctness of his teaching.

Preventive Medicine as applied to Obstetrics.—In England during the last decade the importance of preventive medicine as applied to the pregnant woman has received official recognition, and the responsibility thereof has been vested in the public health authorities. As a result an ever-increasing number of ante-natal clinics have been established.

The common disturbances of pregnancy commence very early; therefore it is all important that women should receive expert advice from the earliest date possible, for the ovum in its growth and maintenance is a parasite, not only drawing on the mother's capital but actually injuring her in many cases by reason of the disturbances it produces in all the tissues concerned with metabolism and this malign process begins at the time of the imbedding of the ovum, when the tissues of the endometrium are digested, and destroyed by the trophoblast, and the end products are thrown into the maternal circulation.

Ante-natal care, in the sense of preventing gross errors is now generally understood and practised, but it is not sufficiently recognised that the diet of the pregnant mother, from conception to parturition, and from child-birth to the end of the lactation, is of immense importance in the prevention of disease in both mother and child.

The work of Cowell, Mellanby, McCarrison and others has indubitably proved that deficiency of vitamines in the pregnant mother not only diminishes her resistance to infection, but predisposes her to infection after delivery. Moreover, the fœtus suffers in its development *in utero*, and should the mother's milk be deficient, or her food scanty, or lacking in fat soluble vitamines A, D, and E, the infant suffers from marasmus and a general feebleness, which is the cause of a considerable proportion of deaths during the first month of life.

These facts are of particular application in India and should be borne in mind by every practitioner, for the strain of pregnancy on

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the metabolism is much greater in tropical countries; moreover, the tendency to toxæmia and infection is likewise greater. The writer has again and again during recent years advocated closer attention to the diet of the pregnant woman, both as regards the conservation of her own health, and that of her child to come. Therefore, at the risk of becoming monotonous, he desires to reiterate that the following diet for all pregnant mothers is recommended, with the addition if need be of cod-liver oil and Parrish's Food for anæmia or diminished calcium content.

Cereals.—Oatmeal porridge or any of the breakfast foods, with milk. Brown or wholemeal bread, toast, rusks, cream cracker biscuits.
Vegetables.—Any vegetable in any form except fried.
Fruits.—Any fruit, either fresh or stewed.
Meat.—Beef, lamb, mutton, veal, not at all; or only very occasionally. Pork never.
Curry never.
Chicken, (avoid duck, goose, or game).
Croquettes or rissoles, if not fried in deep fat.
Eggs.
Fish.—Any fish, except salmon, mackerel and hilsa.
Soups.—Any soup, thick or clear, but free from fat.
Sweets.—Any jam or jelly, marmalade or honey, but pure honey is best of all. Milk puddings. Boiled puddings occasionally. No pastry, no cakes.
Salads.—Any salad, but sparingly of salad dressing.
Fluids.—Water, ærated water, home-made lemonade, orangeade, weak tea, coffe, milk, as desired.
No alcohol of any kind. Butter may be taken if desired, but not in large amounts. Cream, fat meats, and any fish fried in deep fat should be avoided. Fruits and vegetables must be taken at least twice a day, and meat, if at all, not more than once every other day. Mild cheese, such as St. Ivel's is permissible.

It must be remembered that when there is deficiency of vitamines in the food, there is also a shortage of calcium, potassium, sodium, phosphorus, iron, and iodine, etc.

There is good reason to believe that a considerable part of the formidable array of disease, including lack of growth and vitality, that beset the child and adult in the East is caused by food deficiencies and there can be no doubt that there is widespread shortage of vitamines in the diet of the poorer classes, caused by ignorance, poverty and the refinement of food, over which they have no control. For instance the deficiency in vitamine B is mostly due to the refinement of cereals, that is the refinement of flour. The bread made of such flour forms 70 per cent. of the diet of the poor. Wholemeal bread contains seven times as much vitamine B as white bread, therefore it behoves everybody in India to eat wholemeal bread and to supplement the deficiency in vitamine B with dâl or eggs or ata.

Fresh milk and cheese are the foods richest in calcium, and when these are taken in any quantity there will be sufficient calcium in the diet, but it must be remembered that large numbers of poor children get very little milk. The body needs 9 to 15 grains of calcium per diem. A pint of good cow's milk contains 10 grains.

There is very little iodine in the food or soil of Bengal, the lack of which is frequently responsible for lowered and disordered metabolism. This can be made good by taking iodised salt, known as Iodosal, instead of ordinary salt at meal times.

Munro Kerr in a most excellent lecture advocates adequate hospital accommodation for all serious cases which have been primarily seen, in a well run ante-natal department. The importance of such supervision should be generally recognised in India, where the incidence of mal-positions, toxæmias, deformities of the pelvis, and puerperal sepsis is colossal. The writer lays particular stress on the better training of students in clinical midwifery, for the day after he qualifies the practitioner may be called upon to perform a serious obstetric operation which he has never done himself, or even seen performed. He suggests that one whole term of three months should be devoted to clinical obstetrics and gynæcology alone by every student, and that every general practitioner should undergo revision courses in a hospital every three to five years.

Before leaving the subject of obstetrics, the writer would like to refer to the very large number of cases of small round pelvis and contracted outlets that are seen in Bengal. Whitridge Williams considers the generally contracted pelvis to be a stigma of degeneracy, and he produces weighty evidence to corroborate his views.

It may help the general practitioner to remember that in 95 per cent. of all cases the transverse of the outlet corresponds with the distance between the posterior superior spines and if this measurement is less than three inches a difficult or tedious labour is certain.

Puerperal Sepsis.—A review of the recent literature of many countries indicates that the Hobb's treatment of the peurperally infected uterus by intra-uterine injections of glycerine has come to stay, and certainly the published results render it imperative that every practitioner should be conversant with the technique of this lymph drainage method. This has been given in full by the writer in the *Indian Medical Gazette* of November 1926, and it will be sufficient here to refer to the fact that it is very useful in certain cases of sterility, and of subinvolution or menorrhagia after abortion or miscarriage. But of still greater importance is its use in cases of acute puerperal sepsis, for it has not only diminished by one half the number of complications, but has reduced the mortality to one-third of the previous figure.

Phillips, in an address to the Royal Society of Medicine, demonstrated that before instituting this line of treatment, the average stay in hospital, over a period of three years, was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

41.5 days, whereas, since commencing lymph drainage with glycerine, it has been reduced to 26.2 days. He notes that all such treated patients suffer less from pain, and that there is a rapid improvement in the clinical condition, accompanied by a quick fall in the temperature and pulse rate.

Colebrook, working under the Medical Research Council, London, suggests that there is nothing remarkable in the circumstance that a certain number of parturient women become infected by the hæmolytic streptococcus considering that all wounds are infected with streptococci, and the dense overcrowding in our big cities.

He indicates that there is a natural resistance of women in and after labour, to combat all infection by means of a leucocytosis, and one practical suggestion of his the writer has found very useful, namely:—In all cases of difficult or interfered-with labour, he advises an immediate intramuscular injection of 2 or 3 c. c. of nucleic acid (Parke Davis & Co's Solution No. 1; 5 per cent.). Such an injection will double or treble the number of leucocytes in the circulation within 4 or 5 hours. He particularly advocates that in doing a blood culture bacteriologists should inform the clinician how many microbes there are per c. c. of blood, because this information is of considerable value in forming a prognosis. For instance, when only a few streptococci are found in the blood e.g. 1 to 10 per c. c., recovery is not uncommon, whereas if there are 40 to 50 per c. c. the prognosis is hopeless. Moreover, a series of such counts helps one to judge the effect of any particular line of treatment adopted. Colebrook's experience, like ours in India, is that the worst cases of puerperal sepsis are those in which the lochial flow is completely suppressed. For this reason he is of the opinion that the lymph drainage method of Remington Hobbs is a notable advance in the treatment of these infections.

He does not advocate injecting antiseptics into the blood stream for these "internal disinfectants" fail in the crucial test, viz:—their power to confer upon the patient's blood the capacity to kill more microbes than it had before they were administered.

Laboratory research however indicates that there are two measures which may be helpful, namely, blood transfusion, and the use of arsenical drugs of the neo-salvarsan type. It is indeed melancholy, that blood transfusion in India is so unpopular for Major Lloyd, I.M.S. in Calcutta has ably demonstrated its feasability and ease of technique. The writer's experience fully bears this out.

The reason why novarsenobillon (given in one dose only 0.6 gm.), offers more hope of success in the treatment of puerperal septicæmia, is that after its administration the blood serum of actual patients has been proved to have a largely increased power of killing hæmolytic streptococci.

Gynæcology.

Myomectomy, as an alternative to hysterectomy, is receiving more and more attention, particularly in those cases where the presence of fibroids has possibly inhibited pregnancy. The indications lie within the child-bearing period provided that anæmia is not too severe, and that the fibroids are not so numerous or so troublesomely situated that myomectomy is physically impossible, or at least injudicious on account of the inevitable shock.

Women have a rooted and quite natural objection to hysterectomy, therefore whenever possible myomectomy should be done. The ideal incision is an anterior one, combining it with the tunnel method of Bonney. The endometrial cavity has to be opened in many cases, but this need cause no anxiety. The chances of pregnancy occurring after myomectomy under the age of 38, taking the published reports of four surgeons, are roughly 1 in 4.

The writer having done a considerable number of these operations, has come to the conclusion that although at the end of operation, the uterus looks remarkably queer in shape and size, functional capacity is unimpaired. Two cases he lost after extensive removal of fibroids, one from shock, and the other from hæmorrhage. The advent of Bonney's clamp has now however robbed the operation of many of its past dangers.

Hæmorrhagic ovarian cysts are of great interest to the operating gynæcologist but of greater importance to the practitioner, for they are not uncommon, and are the cause of those frequent cases of dysmenorrhœa and dyspareunia coming on some years after marriage. These patients, between the ages of 25 and 45, have never had in their lives anything in the nature of pelvic peritonitis, and yet when examined one finds some indefinite nodular swellings on either side of, or behind the uterus, which are indistinguishable from similar swellings due to old salpingo-oophoritis. But these women have no history of any acute illness.

Hitherto, such cases have been regarded as chronic tubo-ovarian masses of inflammatory origin, and many of them have been neglected under this assumption, with the result that the tumour slowly grows, and may invade the rectum, and cause perforation. These hæmorrhagic cysts owe their origin to the retroperistalsis of endometrial tissue through the tubes into the peritoneal cavity and having reached this cavity, the endometrium, with its glandular element grafts itself on to the front or back of the uterus, the peritoneum, the ovary, or rectovaginal space. This graft is an unencapsuled growth, and forms small

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cysts containing chocolate like material which is degenerated menstrual fluid. As the endometrioma each month increases in size by virtue of its secreting function, it infiltrates the surrounding tissues like a malignant growth, without, however, showing other signs of malignancy, in the form of metastatic growth, or recurrence after removal.

It is this infiltration of structures in the pelvis particularly which makes removal so difficult, for the endometrioma may penetrate the bladder, vagina, or rectum.

Donald, Bailey, and Sampson have demonstrated that endometrium is the invariable constituent of these tumours, and have shown that each tissue will react in a different manner to the growth of endometrium, according to its own structure, for instance, endometrium may be implanted in the parietal muscles after ventrofixation or myomectomy, and then excite muscular fibrous reaction with the formation of a tumour which becomes encapsuled.

In the ovary, on the other hand, as there is no muscle, there can be no reaction of a muscular type, but the endometrium stimulates menstrual function in the formation of cysts: Stevens has suggested that in some cases these displaced fragments of endometrium may give rise to primary malignant growths of the ovary.

Treatment:—As these morbid tumours must have existed from time immemorial in women, it is probable that many undergo spontaneous cure with the natural cessation of menstruation, when the uterus and the ovaries atrophy at the menopause; but if the symptoms are severe and invalidism great, it is not possible to wait for a natural cure. for the tumour may, in the meantime, by virue of its infiltrating capacity endanger life: therefore early surgical removal offers the best means of curing these patients of their pain and discomfort.

The technique of any operation must primarily aim at removal of both ovaries with extirpation of the endometrioma if possible, short of injuring bladder or rectum. These operations are always difficult, owing to the dense adhesion of the ovaries, and the fixation of the rectum to the lower part of the uterus makes hysterectomy sometimes impossible. In five recent cases, the writer was only able to perform supra-vaginal hysterectomy, together with removal of both ovaries and their hæmorrhagic cysts (endometriomata).

The argument against the removal of both ovaries in possibly young patients, carries no weight, because these patients are already sterile, when both ovaries are mere blood-sacs adhering to the back of the uterus or broad ligament; moreover, so far as is known, no lesser conservative operation will cure the patient of her symptoms or prevent recurrence. In those cases where operation is refused, or perfect removal is impossible, the application of radium to the uterus, or *x*-rays to the ovaries, will cure the patient by annihilating the menstrual function, but it must be remembered that electro-therapeutics leave the patient with adherent ovaries and widespread adhesions in the pelvis, which may in themselves be a source of danger later, from intestinal obstruction, chronic invalidism, or discomfort from rectal or vesical pressure.

Varicocele of the Broad Ligament, either of primary nature, or secondary to disease of the uterus or adnexa, has come in for considerable discussion in recent years, and the writer's experience bears out in full the findings of Fisher and Castano, for there is no question that women with this condition tend to drift from practitioner to specialist, and from specialist to quack, because the pathological cause of their symptoms cannot be readily diagnosed. The most common complaint of these women is continuous pelvic pain with rectal and vesical tenesmus immediately before the menstrual periods, which are invariably excessive. Following the periods, there is often a profuse watery leucorrhea, and a "peculiar permanent voluptuous sensation," due to congestion of the plexus of veins around the clitoris, which cannot be readily satisfied, owing to the deep pain during coitus. Physical examination may indicate nothing more than a bulky uterus, possibly displaced, with congested ovaries. The type of patient is the hypothyroidic one. These women haunt continental Spas, and no doubt are benefited by Plombières treatment, but the only real successful treatment is excision of the varices in each broad ligament, exactly as one would deal with the same condition in man.

Many of these patients, because of this voluptuous sensation, practise masturbation, and drift into a state of acute neurasthenia and melancholia. They are by no means uncommonly seen in this country, as is readily understood when one bears in mind the lack of tone of the pelvic muscles and the static pelvic hyperæmia of so many women in the tropics.

The writer has seen many of these cases, and before advising operation, usually suggests the recumbent position with the foot of the bed raised at nights and for four hours during the middle of the day, combined with cold water vaginal douching, and colon irrigation. The patient is instructed to carry out the Stacey Wilson pelvic muscle exercises, which are for the purpose of increasing the muscle tone of the pelvic diaphragm. In some cases the Hobb's intra-uterine glycerine treatment is very useful. Temporary pessary treatment with rubber ring or ball has not given any satisfaction, though some authorities have advocated their use.

Prolapse.—Bullard has published a comparative study of the end results of all the various operations for prolapse of the uterus which are now performed. There are 361 cases recorded, and the operations were performed by 30 different surgeons and have been closely observed in the follow-up clinics of New York. The summary of this extremely interesting and arduous piece of work, carried out during the last ten years, are as follows:—

(*1*) that 95 per cent. of all cases of uterine prolapse are cured by vaginal plastic surgery, and that any failures of prolapse operations occur early.

(*2*) that vaginal plastic work, combined with ligament shortening from above, is satisfactory perhaps in cases of *slight prolapse*, but the careful fascial reconstruction *per vaginam* is undoubtedly responsible for the success.

(*3*) that all gynæcologists to-day have long since ceased to cure descent of the uterus by any form of suspension or fixation by the abdominal route. Careful reconstruction of the various planes of the pelvic fascia, that have become attenuated, over-stretched, or torn, is the *sine qua non* of the operative treatment of prolapse.

The pre-operative responsibilities of the gynæcologist are many, and in India the realisation of this is particularly important, as many of the patients have suffered long, and only extreme urgency of symptoms compels them to seek tardy relief. The writer, while recognising that local examination may take but a few minutes, would like to stress the importance of careful history taking, and a complete physical examination, not neglecting a renal function test, for arterial hypertension is nearly always associated with a subnormal renal function.

If the daily renal excretion of urea in India is less than 250 grains, a blood retention of nitrogenous waste products may be suspected. In this connection, the phenol-sulphophthalein test is a most useful indicator of the metabolic processes, as represented by the kidneys. In all elective operations, results would be considerably improved if for a week or ten days before operation every patient adhered to a salt free diet, ate no meat, and at the same time took, for not less than five days, an alkaline mixture containing bicarbonate of soda, potassium citrate, and glucose.

The essential cause of acidosis is an insufficient utilisation of carbohydrate, because of an inadequate supply of the carbohydrates themselves, or because of the inability of the body to oxidise them. Glucose has considerable value as a diuretic. It counteracts the endogenous destruction of body proteins and aids materially in maintaining renal function, therefore, in any severe post-operative acetonæmia, intravenous glucose is a great standby. It can be now obtained pure in 5 c.c. ampoules from Messrs. Burgoyne and Burbridge, ready to be added to sterile saline for intravenous injection.

The public and many practitioners have become imbued with the idea that *x*-rays and radium can benefit or cure all kinds of pelvic tumours. Nothing could be more erroneous, or in the interests of the patients more disastrous, for many pelvic tumours are associated with pronounced anæmia or inflammatory conditions of the adnexa, which in themselves are contra-indications.

Pyelitis is extraordinarily common in the East after operations. These cases can be guarded against or cured by massive doses of bicarbonate of soda and potassium citrate daily in large quantities of water, (not less than five pints per day), but occasionally the infection resists these measures, and then iodine may be useful. The solution is:—Pure iodine 8 grains, pure potass. iodide 8 grains, in 1 oz. of double distilled water: 10—20 drops, in 30 drops of double distilled water to be injected slowly intravenously once a day for three days. American surgeons, advocate the intravenous use of American mercurochrome, 1 c. c. of a 1 per cent. solution in 5 c. c. of saline, for 3 days. In India, it is no uncommon thing for a patient to present herself for operation with a history of previous *B. coli* infection. The writer has found in these cases that a week's full course of hexylresorcinol (Caprokol) is an efficient prophylactic, for it it would appear to protect the upper urinary tract from *B. coli* invasion. Practitioners should remember that it is a serious error to take a patient off alkalines while there is fever. The acid sodium phosphate and urotropin line of treatment is only to be given when the temperature is normal. Again, never inject vaccines—autogenous or stock—if there is high fever; to do so is to court disastrous rigors.

The Menstrual Function.—In the light of recent research, especially that of Wilfred Shaw, Marshall, Dixon and Beckwith Whitehouse in England; Novak, Allen and Frank in America; and Schroeder in Germany upon ovulation and the development of the corpus luteum, we must regard menstruation as an unfertile abortion of the non-pregnant decidua. Menstruation follows death of the unfertilised ovum, in other words, menstruation is the uterus weeping for the death of an ovum, and this death of the ovum is synchronous with retrogression of the corpus luteum.

Rupture of the ovarian follicle, about the 13th to 17th day of the menstrual cycle, with escape of the ovum and growth of the corpus luteum, initiates development of the premenstrual hypertrophy of the endometrium. Once the ovum is discharged, the duration of its life depends on its meeting and fusing with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the spermatozoon; if it is not fertilised it dies, and the result is retrogression of the corpus luteum, and necrosis of the menstrual decidua, which is cast out. Therefore the old theory that the menstrual function is necessary for the conception of the ovum is a pure myth. This will be readily understood in India, where marriage is often consummated and pregnancy occurs before any menstrual lochia has appeared. Moreover, it is common knowledge that conception may occur during lactation, after the so-called menopause, and during pathological states of amenorrhea. Beckwith Whitehouse summarises the position as follows:—

"The analogy existing between the menstrual abortion, and abortion during the early months of pregnancy, is very striking, when the two processes are compared. In each, there is softening and dilatation of the cervix; in each uterine contractions are present, and in each there is subsequent expulsion of the necrosed decidua. Investigation of the discharge on the second or third day, after an early complete abortion, shows that it has much in common with the menstrual lochia. Menstruation is, in fact nothing more than the disorderly action of a disappointed uterus; or perhaps shall we say, of a disappointed ovum."

The association of the ovary with the accessory genital glands, notably the thyroid and pituitary, is of increasing importance. Virchow stated "woman is a pair of ovaries, with a human being attached, whereas man is a human being, furnished with a pair of testicles." But evidence is accumulating that the ovaries are but a single link in the mechanism responsible for the metabolic rhythm of the adult female.

It is probable that the thyroid initiates the maturation and rupture of the first ovarian follicle, and is therefore responsible for the first menstruation and development of the first corpus luteum, with the institution of the sex cycle. This cycle, intimately associated as it is with variations in the basal metabolic rate (Wakeman, Heilig and Bond) testifies to the wisdom of Blair Bell's dictum "propter secretiones internas totas, mulier est quod est" (her internal secretions make a woman what she is).

Beckwith Whitehouse groups all pathological uterine hæmorrhages under four headings, which respectively convey a definite pathological entity.

1. *Epimenorrhœa*, or too frequent periods, is the clinical manifestation of a hyperactive state of the sex complex. It means that the ovaries are working at too high pressure, and producing ova of too low vitality, with the natural result of frequent menstrual abortions. This is the condition so frequently present shortly after matrimony, and so common in India during the cold months. Curettage for such a condition is of course useless, for the ovaries are hyperplasic and often polycystic. Epimenorrhœa also occurs at the end of sexual life, when the sex rhythm tends to become disordered. It has been suggested that therapy directed towards inhibition of the accessory sexual glands, e.g.—*x*-rays to the thyroid, is the best method of treatment, but this treatment has its dangers.

2. *Menostaxis*, or prolonged periods, which last from seven to twelve days or longer. The symptoms do not occur with every period, but often there is a history of several prolonged periods in the same patient. It is thought that the corpus luteum is associated with this type of hæmorrhage; although curettage frequently cures the condition, clinical experience, shows that recurrence of menostaxis is very common; and which vaginal hysterectomy or radium may be necessary.

3. *Menorrhagia*, or flooding, is merely a severe menstrual hæmorrhage, due to what may be termed uterine insufficiency, and is associated with chronic subinvolution, and changes in the uterine wall related to chronic metritis. In exceptional cases, it may be due to the uterine insufficiency of adolescence. This is a serious condition. Curettage is of only temporary use, and although thyroid radiation has been recommended, it is probable that intra-uterine application of radium is the best therapeutic measure short of vaginal hysterectomy.

4. *Metrostaxis* is the term used to include all hæmorrhages independent of the menstrual cycle. In this condition, the hæmorrhage is severe, and bright red with frequent clots. The endometrium is hyperplasic and almost polypoid. Beckwith Whitehouse considers that the problem of metrostaxis will not be completely understood until more is known of the innervation of the uterus, and the function of the autonomic nervous system, in so far as it controls the internal genital organs, possibly through the thyroid gland.

It is not surprising that the endometrium should be particularly susceptible to outside influences, when the embryonic nature of its structure is taken into consideration. "The uterus," as Cullen wittily remarks, "is an organ upon which many tunes are played." We have therefore, as clinicians, to bear in mind not only the instrument, whether it be good or bad, but to direct our attention to the technique of the artist, and to remember that a woman may possibly blush with her uterus as well as with her skin.

The conclusions of Professor Whitehouse, are as follows:—

(1). Menstruation is the monthly abortion of the decidua of an unfertilised ovum.

(2). The menstrual discharge is the lochia of an unfertile abortion.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(3). The premenstrual endometrium is the menstrual decidua, and its development and life are dependent upon the corpus luteum.

(4). Menstrual abortion is initiated by the death of the unfertilised ovum, and retrogression of the corpus luteum.

(5). Epimenorrhœa is the clinical manifestation of hyper-activity of the sex complex.

(6). Menostaxis is an incomplete unfertile menstrual abortion.

(7). Menorrhagia is the result of uterine insufficiency, which may be (*a*) developmental (*b*) inflammatory, (*c*) degenerative. This insufficiency may be associated with lesions in (*1*) the metrium, (*2*) the endometrium.

(8). Metrostaxis is the reflection of outside influences upon the uterus, commonly associated with functional hyper-thyroidism, and hyper-sensibility of the sympathetic nervous system.

(9). Estimation of the blood tolerance of sugar, and the basal metabolic rate provide valuable data in the investigation of uterine hæmorrahge, especially at the time of puberty and the menopause.

A SHORT ACCOUNT OF THE WELSH MISSION HOSPITAL, SHILLONG, AND A RESUMÉ OF ITS WORK.*

By H. GORDON ROBERTS, M.D.

I HAVE great pleasure in responding, although with much hesitation, to your very kind suggestion that I should give some account of the history and work of the hospital with which I am connected.

The history of the Mission Hospital in Shillong differs, I suppose, but little from that of many similar institutions. What impressed one most when first coming out to India was the extreme unwillingness of the sick to become hospital in-patients. We were given to understand by those who spoke from experience that the sick in India, as a rule, much preferred to attend an out-patient dispensary than to become in-patients of a hospital ward. While enthusiastically supporting the case for the fullest development of out-patient work, we were deeply impressed by the necessity for making adequate in-patient provision in order to secure the best results in many cases.

Our work began in a two-roomed cottage and the beginning was a very small one. We received very great encouragement and help, in planning the new hospital, from Lieutenant-Colonel Innes, I.M.S., the present Inspector-General of Civil Hospitals, Assam, who was at that time the Civil Surgeon of Shillong. During the war, the building operations were slowly carried on. It was only after building for some time that one realised how much money would be required if the work was to be satisfactorily completed. Backed by a generous capital grant from the Government of Assam, which was given on the strong recommendation of Colonel Sir H. E. Banatvala, I.M.S., who was the Inspector-General of Hospitals at that time and to whom the hospital is greatly indebted, an appeal was issued to the friends of the Mission in Wales for the sum of £20,000 with a view to the completion of the scheme and the provision of the nucleus of an Endowment Fund, and in response over £30,000 was given. The contributions very largely took the form of endowments of beds and cots. While home on furlough we received very valuable help from the Commissioner of Housing for Wales who gave freely of his time and expert advice and helped us to secure electrical and sanitary equipment on the most favourable terms.

In March 1922, the Hospital was opened by His Excellency, Sir William Marris, Governor of Assam. He offered the best wishes of Government on the new venture and inaugurated a Fund in India to which he contributed Rs. 5,000. Comparatively little headway was made during the eighteen months following the "Opening Day." It may be of interest if I now mention briefly some of the features of the hospital.

Buildings.—The main building consists of two medical wards, two surgical, and a large maternity ward; this latter is a recent provision. In addition there are eight private wards, consulting rooms, with special eye, nose and throat room, together with a large dispensing room, laboratory, and out-patient's dressing rooms.

Entirely separate from the main building is the "Annexe" which contains four wards. Special attention has been given to proper and adequate ventilation; hot and cold water pipes throughout, including modern

Photo 1.—The Khasi Hills Welsh Mission Hospital, Shillong.

---

*A paper read at the annual 1926 meeting of the Assam Branch of the British Medical Association, and re-printed from its *Proceedings* by kind permission of the President and Council of the Assam Branch, B. M. A.

Digitized by Arya Samaj Foundation Chennai and eGangotri

baths, etc., have been fitted, so that nothing may be lacking to promote cleanliness. The hot water supply is obtained from two boilers, the larger of which is capable of an output of about 300 gallons per hour.

Septic Tank.—This provision has been laid down on modern lines and includes frequent manholes. Numerous "sanitary" latrines and five "modern" bed pan flushing sinks serve the septic tank.

Lighting.—The hospital and its adjoining buildings are lighted throughout with electricity, and, in this connection, it is to be noted that the whole of the electrical installation including the erection and setting up of two engines and power-house has been done by Khasis, as indeed has been the case with the whole of the scheme with the exception of the sanitary installation.

Laundry.—This work is all carried out on the premises and not by "dhobies" as is the usual custom. Special provision has been made for the proper soaking and boiling of hospital linen. Electric ironing can be done when required.

Operating Theatre.—No reasonable expense has been spared to make the operating theatre as up-to-date as possible. It is supplied with the usual fittings and the various sterilizers are all worked by electricity from the 60-cell hospital battery. There is an adequate number of instruments for general and special surgery. The heating is secured by hot water pipes and movable electric radiators.

Photo 2.—Electric Sterilising Room.

X-Rays.—Two machines have been installed. The larger is a high-tension transformer which has considerable penetrating power and gives very satisfactory screen illumination. The smaller is used for therapy and as a spare.

In addition a certain amount of electrical apparatus has been installed and it is hoped that before long the diathermy and high-frequency apparatus already provided will be in proper working order.

Nursing Arrangements.—The initial provision of one European sister being insufficient, a second sister was appointed and it is anticipated that the number will be increased to three at an early date.

The hospital was opened with 4 to 5 Indian Christian nurses under training. The progress of the work has necessitated a marked increase in their number, which now stands at about 40. They are drawn from various parts of the Khasi Hills and at the present moment there are also three from Lushai.

We hope that they will be of considerable value in the various districts from which they come on the completion of their training. Speaking generally, they are wonderfully efficient and reliable. As an instance it may be mentioned that the operating theatre is almost entirely in the hands of the Indian nurses who are able to prepare for the larger major operations. Quite recently in the temporary absence of the European sister three gastro-jejunostomies were performed with no other assistance than that of two or three Indian nurses who did exceedingly good work. Their ward work is uniformly reliable and they keep the various chart records in a most trustworthy manner. The arrangements provide for day and night nursing and include three shifts in every 24 hours. The nursing course is for a period of not less than four years and includes maternity training. A written and practical examination is held at the conclusion of each year's work. The results so far have been most encouraging.

It is worth noting that the supply of nurses is greater than the demand. Girls of quite good family are becoming increasingly anxious to enter the nursing profession. All bed pan and other attendance is rendered by the nurses, and the sweeper (we only need one for the whole hospital) is not ordinarily required to enter the wards which are cleaned by the ward maids as at Home.

The hospital as originally planned was intended for and is being chiefly used by the people of the Khasi Hills. We are, however, very glad to find that the sick of some of the other hill tribes and of the plains are seeking admission also.

Furthermore, in response to a demand from the European community, a European block has been erected and is at the present moment being extended.

Maternity Ward.—This is the most recent addition and it promises to meet a very real need. An up-to-date labour ward has been added, capable of accommodating at least four patients, if necessary, at the same time. A beginning has been made with ante-natal work and it is hoped that there will be a big extension of this department before long.

Altogether the hospital contains about 110 beds, but the number of patients admitted during the summer months may be over 140.

The in-patients admitted during the past three years have been as follows:—

	1923.	1924.	1925.	Total.
Indians ..	513	768	857	2,138
Europeans ..	32	84	95	211
	545	852	952	2,349

A Resume of the Work.

It is exceedingly difficult to lay before you, in a clear and logical manner, the various results of the work and I crave your indulgence and generous forbearance while I try to touch on a few points which may be of some

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

interest or stimulate discussion. As you are aware, the remarks made are based upon a very limited experience.

In turning first and quite briefly to the medical side of the work, I would like to refer to enteric fever. Prior to the opening of the hospital we were greatly concerned by the prevalence and heavy mortality of enteric fever. Things were so bad about 1917 that, when I was acting Civil Surgeon of Shillong, I assisted Major Knowles, I.M.S., who was then Director of the Pasteur and Research Institute, in a big campaign of "T. A. B." inoculation. Altogether about 2,000 persons voluntarily submitted themselves for inoculation, and if I am not mistaken such an extensive T. A. B. inoculation amongst the civil population was unique in India. The vaccine was so potent and inevitably so fresh that we congratulated ourselves that a very large percentage submitted themselves for re-inoculation. Enteric fever is still quite common in many parts of these hills.

An increasing number of the cases are now being brought to hospital and our figures shew a greatly reduced mortality as compared with the cases previously treated outside hospital. The nursing staff is protected by annual re-inoculation and so far has entirely escaped the disease.

In 1924, 21 enteric cases were admitted and 18 were discharged cured. Three died. In 1925, 43 cases were admitted and 38 were discharged cured. Five died. Almost without exception the cases that died were admitted late on in the disease. The almost invariable complication was hæmorrhage and if this occurred in a case that had been on full diet before admission a fatal result generally followed. Nearly every case admitted early in the disease recovered, and we attribute this result very largely to the nursing care, with constant day and night watchfulness and the careful prevention of any food being brought in by the patient's friends. One of the fatal cases was a European patient who was brought to us for laparotomy after she had perforated. It is the only case of perforation that we have seen in over 12 years.

B. Coli Infection.—You will all agree that we are exceedingly fortunate in being in such close proximity to the Shillong Pasteur and Research Institute. We have benefited immensely as a result of the extreme readiness of the various Directors to examine our numerous specimens and in particular we wish to offer our most sincere thanks to Lieutenant-Colonel Hodgson, D.S.O., I.M.S., for all that he has done for us during the recent past. It is only recently that we have discovered that *B. coli* infection is very widespread and we are realising the value of a cultural examination of the urine in many of our cases. A sudden and more or less persistent pyrexia immediately following a normal confinement attended in hospital; a sudden malaise with pyrexia and throat symptoms occurring perhaps three weeks after an otherwise uncomplicated gynæcological operation; a dull and unexplained pain persisting often in the left renal region may prove to be the recrudescence or persistence of an old *B. coli* infection. Almost all urines are examined on admission and suspicious cases sent for culture. We have had some excellent results following vaccine treatment and have great faith in it. Especially in the acute cases.

There are numerous other medical troubles to which I would like to refer but time will not permit.

Turning now to the subject which is uppermost in the minds of some of us, shall we glance at a few of the surgical possibilities of the work?

Electrolytic Chlorine.—After many years' experience of the more usual antiseptics which form a fairly heavy item in the drug bill we have been altogether won over to the almost universal use of E. C. Those who are familiar with the articles regarding E. C. which have appeared in the *Indian Journal of Medical Research* and the *Indian Medical Gazette* will know how indebted we all are to the indefatigable labours of Mr. C. H. Hutchinson. We use it in various strengths in every part of the hospital. It is invaluable in the out-patient department. We apply it pure as a compress to the skin on the day preceding all operations. It is again applied pure on the table. After application we carefully dry the skin with a sterile dab before making the incision as we do not care for its lymphogogic action in clean wounds. To all septic wounds it is applied in a strength of from 1 in 3 to 1 in 100 or sometimes much weaker. If used for flushing out joints we prefer to follow up with a second douche of ordinary saline. To refer to a recent case—a Khasi youth was admitted with an extensive incised wound of the knee produced by an axe. The patella had been divided longitudinally and the capsule of the joint widely opened. The above treatment was applied on admission (6 or 8 hours after injury) and the divided patella united with silver wire and the wound closed with drainage. The wound healed almost by first intention and the joint entirely escaped infection. For the hands in a strength of about 1 in 100 we use it for almost all our work. We would strongly recommend those who have not given it a trial to do so.

General Surgery.—All those who have any experience of the practice of surgery in this country will probably agree that it takes a considerable time to win the confidence of one's patients. Often the glint in the surgeon's eye seems to "signal" danger ahead to many a poor seeker after "medical treatment only." The secret we find is to go slowly and admit patients "for more careful examination." Our advice is "Don't put them in a ward in which other patients are just coming out of an anæsthetic." Moving very slowly from the time when we sometimes had to spend hours trying to get a patient to consent to an operation we have gradually attained to a much more hopeful state of affairs as is instanced by the words of a recent patient who said "Are you only offering me medical treatment?" We were assured when we first started work that there was very little surgery in the hills of north-east India. By dint of steady enquiry, in which knowledge of the language greatly assists, and patient investigation, we have discovered that there are far more surgical cases in the land than we had at one time supposed. Shall we again make brief reference from a small selected list? As you will agree it is not possible in a paper of this kind to go into much detail. Apart from the numerous minor operations the following operations were performed:—

1923	176
1924	198
1925	280
Total ..	654

Abdominal Surgery.—The work done under this head is gradually increasing:—

Abdominal sections performed in 1923 numbered	63
Abdominal sections performed in 1924 numbered	90
Abdominal sections performed in 1925 numbered	102
Total ..	255

It may be mentioned that the anæsthetics for all operations upon Indians and Europeans have been efficiently given by Khasi Sub-Assistant Surgeons attached to the hospital.

In 1925, 66 appendectomies were performed. Of this number—

(*A*) 17 were uncomplicated appendix disease.
(*B*) 15 were removed during the operation of gastro-jejunostomy.
(*C*) 34 were removed during various gynæcological operations, etc.

Fully 90 per cent. of the appendices removed under the heads B and C were definitely diseased.

The operations have proved beyond question that appendicitis is a very common trouble at any rate in the Hills. It is, however, much more common in its chronic

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

than in its acute form. Obviously one does not wish to be dogmatic as to the etiology. One expects it most in cases of chronic constipation, and it appears to very readily follow an attack of enteric fever or dysentery. One wonders how far a liberal diet of pork and dried fish can influence it. We have had many cases of so-called "chronic dyspepsia" which have been cured or greatly relieved by the removal of the appendix. In some of these cases the barium meal shews stasis of the colon and often considerable ptosis.

We see quite a large number of tubercular abdomens, arisen from bands in the ileo-cæcal region following old appendix mischief. Some time ago a patient was admitted at midnight in intense abdominal pain and with complete obstruction. He gave a history of chronic dyspepsia but was otherwise quite fit until 4 p.m. on the same day. He was prepared for operation (our theatre equipment allows us to operate as easily by night as by day) and a laparotomy was performed. His condition was very grave and we were afraid that he might die on the table. Loops of greatly distended gut made investigation very difficult. Ultimately the obstruction was discovered near the ileo-cæcal valve where adhesions had arisen around a chronically inflamed appendix. The distension was so great that the gut had to be opened and emptied before the abdomen could be closed. To our surprise he made a straightforward recovery. We have had a fair number of cases of acute appendix trouble, chiefly amongst the tea-planting community. Government officials seem to be strangely immune!! Some time ago we had a case of very acute appendix in a European patient. She had suffered from chronic pain for about 25 years, in the right illiac region, which she had been told before she was married was of ovarian origin. When she was 47 the trouble suddenly lit up in the most intense manner. She reached us on the sixth day. Fortunately resolution started and so operation was postponed. It was six weeks before we dared venture to open the abdomen. It was the most difficult case that we have ever seen and the operation lasted 2¾ hours. Everything was matted together and the distal portion of the appendix was larger than one's thumb and contained a very hard concretion about the size of a large gallstone. After one or two stormy days she made a good recovery.

We see quite a large number of tubercular abdomens, and, frequently, deposits around the ileo-cæcal valve and in the neighbouring glands *simulate* ordinary appendix mischief plus chronic malaria. We have been surprised at the number of cases which are complicated by tuberculosis of the abdomen. We have found that the early cases often clear up after exploratory laparotomy. Unfortunately the great majority are very extensive and laparotomy has not been of much value in these extensive cases. We have started performing resection of the cæcum and ascending colon for tubercular disease which is localised to this area. We have a case waiting for such treatment at the present time. Laparotomy, a few weeks ago, revealed tubercular trouble in the cæcum and the last few inches of the ileum only. At the time her condition contra-indicated resection. She is now much better but the persistence of her pain makes her wish for further treatment.

Gastric and Duodenal Ulcer.—Another subject which is at present claiming a good deal of our attention is ulcer of the stomach and duodenum. On first coming out to India we were told that almost all epigastric discomfort and pain was of hepatic origin. Personally I used to marvel at the skill of some clinicians in palpating the liver, especially with the patient standing! It seemed quite reasonable that, in a land where malaria and dysentery are so prevalent, the liver should very often be at fault. In the early years of one's work in this country there were many cases of "hepatic dyspepsia" where the diagnosis was often arrived at far too hurriedly and one often wondered at the frequency of "hepatic tenderness" During the past five years we have been slowly proving that many of these so-called cases of "hepatic dyspepsia" are definite cases of gastric and duodenal ulcer, frequently complicated by chronic appendix disease. At first we only operated upon those cases which were clinically very definite. But of late, with the assistance of the confirming "barium meal" we have been operating upon an increasing number. We have gone very slowly and very carefully and have only chosen surgical treatment in really convincing cases, so much so that in every case operated upon, so far, we have discovered an ulcer. In 1925, 19 gastro-jejunostomies were performed and this year we have have operated upon 12 cases, to date (March 31st, 1926). The gall bladder is carefully examined in all cases and, although it is sometimes affected, we have been surprised by its freedom from any marked disease. As our cases so far comprise Khasis, Lushais, Nagas, the people of the plains and Europeans, it may not be out of place if we pause to consider the subject.

Symptoms and Signs.—The most frequent symptoms is pain centering in the right epigastric region but radiating in many directions. Quite recently we had a case where the pain was chiefly in the sigmoid.

Tenderness.—It would appear that some teaching suggests that *superficial* tenderness ought normally to be elicited in the presence of an ulcer. This may be true of an acute ulcer. We frequently find that chronic ulcers when first admitted may be associated with marked superficial tenderness but on low diet the tenderness gradually becomes less marked until it is often difficult to elicit even deep tenderness. In some cases there is no tenderness.

Vomiting.—We have not found this a very common symptom except of course in the cases of partial or complete obstruction.

Hæmorrhage.—This is infrequent.

"Barium Meal" examination.—During recent months this has been done systematically. We have found it the greatest possible help in diagnosis. A considerable number of the cases show "delay" in the stomach up to 5 or 6 hours. In a recent case of ulcer of about 14 years duration there was delay in the stomach for over 24 hours. Typical incisuræ were very seldom seen on the screen but hyperperistalsis was quite common and usually began about 5 to 10 minutes after the administration of the meal.

As a matter of interest it may be noted that ptosis of the colon was frequently observed.

Treatment.—A good deal of medical treatment has been tried and in some cases for many months, but the results have been generally very disappointing. A return to ordinary diet was generally followed by a return of the symptoms. We have come to the conclusion that surgical treatment is by far the best and the operation usually performed has been posterior (no loop) gastro-jejunostomy. In a few cases the size of the ulcer or the extent of the adhesions necessitated the performance of the anterior operation. The majority of the ulcers were not more than ½ inch in diameter, but a few were very large, and in one case about half the size of one's fist, including the surrounding inflammatory mass. The majority of the gastric ulcers were on the lesser curvature near the pyloric ring. The duodenal ulcers were mostly in the second part of the duodenum. Only in a few cases was there gall bladder involvement and in these cases the ulcer was generally adherent to the liver. Under such circumstances it is easy to understand the difficulty of diagnosis. The results have been very encouraging and about 95 per cent. have been either cured or immensely relieved. It is too soon for us to attempt to speak much about the more remote results which we hope to report in course of time. There are many points in the post-operative treatment to which one would like to refer but time will not allow more than one brief reference. In a young European patient (who had previously undergone surgical treatment for appendix abscess) the adhesions made the operation unusually difficult. Serious regurgitant bilious vomiting set in about 24 hours later. On the 5th day a secondary operation had to be performed and a secondary anastomosis made between the fourth part of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the duodenum and the jejunum. This allowed the bile to pass and she made a good recovery.

Gallstones.—This trouble seems to be strikingly absent, but we have had a few cases even amongst Indians. The cases seen were all associated with sclerosis and contraction of the gall bladder. In one case there was a large stone impacted in the hepatic duct but the patient's condition did not permit of more than cholecystotomy. We have a case in hospital at present. A few weeks ago she was admitted for pain and severe vomiting. The diagnosis lay between gallstones and ulcer. When placed on the operating table she had no pulse in the right wrist and a very feeble one in the left. On opening the abdomen we found an ulcer on the lesser curvature, which was adherent to liver, plus a thickened gall bladder with 5 or 6 stones. Her condition did not permit of both cholecystectomy and a short circuit operation and so the latter was chosen. She did very well after the operation but was still on the lowest possible diet on the tenth day, when she had a sudden terrible hæmorrhage from the ulcer which deprived her of about three pints of blood. In desperation we washed out the stomach when she appeared to be on the point of death. The hæmorrhage stopped but we did not expect her to live the night. Strange to say she recovered and is doing fairly well. As soon as her condition allows we hope to remove the bladder and stones. I think you will agree that cholecystotomy is not sufficient in such cases. In another case we were scooping out stones from the gall bladder when something string-like was detected adherent to the wall. A finger was inserted and to our surprise a long but dead Ascaris was delivered. It had evidently gone up the bile ducts and perished in the gall bladder. In passing one may mention that round worms in the gut often deceive the finger when trying to deliver the appendix through a small wound.

Urino-Genital Surgery.—It is interesting to note that so far we have not discovered* a renal or ureteral calculus in any of our Indian patients. We have had a few cases of pyonephrosis but without evidence of associated stone. We have carefully scrutinised the radiographs in suspicious cases but there have not been any convincing shadows.

Vesical calculus on the other hand is fairly common. We find *x*-rays of value in these cases, more in the presence of multiple stones or an encysted calculus. As all will agree the diagnosis is usually confirmed by a finger in the rectum or by the sound. In a few cases we cut for stone but in the great majority litholapaxy is performed. With small lithotrites we have crushed stones in children of 2½ years. When compared with districts like the Punjab our stone work is of course very small.

To pass rapidly on, it may be mentioned that we have a few cases of hydrocele, hernia and undescended testicles; enlarged prostates are very rare. You may be interested to know that we recently operated upon a case (the only case that we have seen in India, and sent to us by Dr. Foster) of ectopia vesicae in a young boy. Moynihan's modification of Maydl's operation for transplanting the whole bladder into the rectum was performed. The operation was satisfactorily completed and urine was passing per the urethral catheters which were brought out through the anus but unfortunately the patient was in a very poor state of health and died of shock. In a subsequent case we would be inclined to perform the operation in two stages unless the patient was in good health. We have recently had amongst our hill patients two cases of scrotal elephantiasis. Both were treated by excision of the scrotum and penile decortication and subsequent grafting from the thigh. The first case did very well and the patient recovered from his sexual debility. The second case is doing well but is still in hospital. We are sometimes called upon to perform a Wheelhouse operation for stricture but we have not found this operation so commonly required as it is at Home. Cancer of the penis is rare. Recently we had a case where total extirpation was performed and the urethra transplanted about an inch in front of the anus with resultant excellent urinary control.

Photo 3.—A case of elephantiasis of the scrotum and penis. The patient had lived all his life in the *hills*. Operation with good result; sexual power recovered.

Surgery of the Chest.—Resection of ribs for empyema is in our experience a very rare event. We had a recent case associated with traumatic fracture of the ribs from a fall. After a prolonged convalescence the patient made a very good recovery. For the few cases of tropical abscess that we get we prefer the open operation, if possible, through the chest wall.

Orthopædic Surgery and Fractures.—The opportunities in this direction are increasing and we are obtaining a considerable number of these cases. There is a growing tendency for such cases to submit to surgical treatment. Arthritis deformans is frequently seen. Dental sepsis is quite common and we gather that there is a good deal of intestinal toxæmia amongst many of our patients. The shoulder and knee joints seem to be most often involved. For knees, fixed in a flexed position, we sometimes do a partial excision of the knee and the leg is then fixed in extension. We are getting an increasing amount of talipes to treat, and have frequently found it necessary to do tenotomy and apply plaster of Paris casts. These cases have done very well.

Amongst old unreduced dislocations we managed to reduce a dislocation of the jaw with a three months history. An old-standing dislocation of the hip was

* Since this was written we have had a case of renal calculus.

Photo 5.—A patient aged six years with a large sacro-coccygeal tumour. Removal, with excellent result.

successfully reduced by open operation but the prolonged manipulations appeared to have induced considerable shock from which the patient died. The patient was very much disabled and surgical interference was only tried when other methods had failed.

We are attempting operation upon a certain number of malunited or un-united fractures. By a rigid aseptic technique we have had some success with wiring and plating bone and we are inclined to recommend it in certain cases. For instance, a case of un-united fracture of the femur in its lower third with wide separation of the fragments reached us five weeks after the accident. With great difficulty the fragments were brought into alignment and Lane's plates applied; (the case seemed to require Hey Groves double plates and bolts but we were without them at that time). The leg was kept in plaster for about six months before union occurred. While in hospital, the patient developed appendicitis, so, before he was discharged, we removed both the Lane plate and the appendix at the same time. He is now walking about but with a little shortening.

We get a fair amount of tuberculosis of the hip, knee and ankle. A case of early tuberculosis of the knee which was kept in plaster for nine months entirely recovered. Surgical removal during the active stage has very disappointing results. For healed tubercular hip with deformity we have found sub-trochanteric osteotomy quite satisfactory. We see very little tuberculosis of the spine but we had an advanced case recently. We made a spinal frame but the case went steadily to the bad.

Naturally we find *x*-rays of great help to our orthopædic and fracture work.

OBSTETRICS AND GYNÆCOLOGY.

No reference has been made to gynæcology and obstetrics, which forms our chief work. In the hills, women come to hospital with the greatest readiness. We have therefore excellent opportunities for the study and treatment of women's diseases. Uterine disease (and displacement) is exceedingly common. Many hundreds of pelvic examinations are made every year and we meet with a great many uterine displacements which are more or less symptomless. Sacral ache, dysmenorrhœa and menorrhagia are, however, very frequently associated with uterine displacement or disease. The operations of dilatation and curettage, perineorrhaphy and ventro-suspension of the uterus are frequently performed. We have attended a considerable number of deliveries in patients previously ventrofixed and have not seen any trouble in labour. Hysterectomy, saplingectomy and ovariotomy are performed less frequently. During 1925 we operated twice for ruptured extra-uterine gestation and also performed Cæsarean section twice and Cæsarean section followed by total hysterectomy once. One case of Cæsarean section was performed about 7 minutes after the death of the mother who died quite suddenly in her first eclamptic fit. The baby is still alive and doing well. A few cases which might have been treated by Cæsarean section reached us with a frank infection necessitating craniotomy. We are trying to establish regular maternity work and we are getting a steadily increasing number of "normal" cases especially amongst primiparæ who are not so hindered from entering hospital as are the multiparæ with their domestic ties. The following figures show the progress of the maternity work during the past three years:—

	1923.	1924.	1925.	Total.
Normal ..	30	42	57	129
Abnormal ..	13	25	23	61
Total ..	43	67	80	190

The growth of the maternity work is giving greater opportunities for the training of our nurses. An increasing number of pregnant women are attending the out-patient department where they receive antenatal care, have their pelvic measurements taken and their urine examined. A great deal has still to be accomplished and we admit many women for further treatment

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

who have suffered seriously from long or untreated labours in their own homes. Vesicovaginal fistulæ are far too common and the variety that we generally see is that which is associated with destruction of the internal sphincter. We attempt operative treatment, but so far the results have been disappointing.

Photo 6.—A Khasi nurse looking after a European baby.

I fear that I have already trespassed far too much upon your valuable time and although there are still many matters such as cataract and other eye troubles, that might be referred to, I will draw to a conclusion.

Before doing so it will not be out of place, perhaps, if a word is stated about cancer. In the past twelve years I only remember seeing one case of cancer of the breast and not more, I should say, than a dozen cases of uterine cancer. We do not see much intestinal cancer but we see a few cases of gastric cancer. One of our gastro-jejunostomies in 1925 was for gastric carcinoma which had produced almost complete pyloric obstruction.

The most common form is cancer of the cheek and lips. One would suspect that it is influenced by the very common habit of chewing the betel-nut. We have had a few early cases where operation was performed. Many arrive after they have passed into the inoperable stage. We see a fair amount of sarcoma. The face, neck and upper extremity are chiefly affected. *X*-Ray therapy has caused a few of these growths to disappear in a remarkable manner, sometimes only to return later. You may also be interested to know that we have found *x*-rays of much value in reducing the size of some enlarged spleens, especially malarial spleens. In one of Lieutenant-Colonel Hodgson's cases of kala-azar the spleen was greatly reduced by *x*-rays after other treatment had failed.

In conclusion it may be stated that the upkeep of the hospital requires over Rs. 50,000 per annum. The Mission is only able to contribute about Rs. 8,000 of this amount and so our income has very largely to be raised from the fees of private patients. We receive many generous gifts from grateful patients.

Current Topics.

The British Social Hygiene Council.

A DEPUTATION of the British Social Hygiene Council, consisting of Dr. David Lees, D.S.O., F.R.C.S., and Mrs. Neville Rolfe, O.B.E., are at present touring India, and will be in Calcutta from January 27th to February 17th, 1927.

During their stay in Calcutta they will give a series of lectures and addresses to medical and lay audiences, dealing with various aspects of the campaign against venereal diseases. Dr. Lees will visit the hospitals and medical colleges and schools in Calcutta, and will give a series of post-graduate lectures to medical men at the Overtoun Hall, 86A, College Street, on February 1st, 3rd, 7th, 9th and 11th, at 6-30 p.m. These lectures will deal with modern methods of diagnosis and treatment of venereal diseases, and are illustrated by cinema films They are likely to prove highly interesting and instructive, and all medical men are cordially invited to attend.

Stovarsol in Benign Tertian Malaria.

AN interesting article on this subject is one by Dr. Ch. Vialette in the *Bulletin de la Societe de Pathologie Exotique*, Vol. XIX, No. 5, 1926, p. 359. The author studied the effects of Stovarsol treatment in 47 cases of benign tertian malaria—41 of them Europeans and 6 Africans—admitted to hospital at Rabat in North Africa. The majority of the cases studied were patients who had already passed through the first phases of invasion and who showed an established infection. Results were controlled by microscopic examination of the blood before and during treatment. At first Stovarsol was administered intravenously, but the author very soon abandoned the intravenous route in favour of oral administration, giving an average dose of one gramme daily for four days, then after an interval of five or six days a second similar course.

In the majority of cases it is reported that after the administration of 1.5 gm. to 2 gm. fever disappeared; sometimes 3 gms. were necessary to produce this effect; occasionally fever persisted after the latter dose, but an intravenous injection of Stovarsol then usually effected cure. On the other hand the disappearance of parasites was far less rapid. The author concludes that "Stovarsol has a rapid and favourable action in cases of benign tertian malaria. After a few doses the febrile rhythm is broken and the parasites disappear from the circulation. But in order to secure complete cure it is necessary with Stovarsol—as with quinine—to push the drug and to give repeated doses over a sufficiently long period." Stovarsol is about equal to quinine as a therapeutic agent in the treatment of benign tertian malaria; in chronic and relapsing malaria it is possibly even better. The drug is more easily taken and tolerated than is quinine.

Dr. Vialette's paper is admittedly a preliminary communication only, but it is of interest. The alkoloids of cinchona still remain the sheet-anchor of treatment for malaria, especially when administered with alkalies—as pointed out by Acton and by Sinton. Yet arsenic has a very definite value in the treatment of malaria;—in the reviewer's opinion more as a hæmatinic tonic after the treatment of malaria by quinine than as a direct line of treatment. The value of Stovarsol appears to lie in its high content of arsenic in organic combination; it is easily taken and well tolerated. It would be of special value in cases of malaria complicated by syphilis or by *Entamœba histolytica* infection.

The Wellcome Historical Medical Museum.

No science is more ancient and of more human interest than that of medicine; hence the particular fascination of delving into its rich and varied past. And the medical visitor to London cannot do better than spend an hour or two in the Wellcome Historical Medical Museum, 54A, Wigmore Street, London, W.1. This Museum has always been a joy and a delight to wander through. It has recently been re-opened on October 14th, 1925, at a ceremony presided over by Sir Humphry Rolleston.

The Museum contains an extensive collection of rare objects, pictures, sculptures, manuscripts, early

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

printed books, etc., illustrating the evolution and practice of medicine and allied sciences throughout the world from prehistoric times, and includes a section dealing with primitive medicine, surgery and the healing arts amongst savage and semi-civilised peoples of to-day.

Special sections are devoted to memorial collections of objects originated by, used by, or associated with eminent men who have made history by their great achievements in medical science. These include Dr. Edward Jenner's relics, original manuscripts, instruments, etc., connected with his development of vaccine treatment for small-pox, and also Lord Lister's original appliances, chemical reagents and other materials which he used in the development of his methods of antiseptic surgery as practised by him in the "Lister Ward" of the Glasgow Infirmary and elsewhere. A portion of the original "Lister Ward," reconstructed from the actual material and fitted with the original equipment, forms an important exhibit in the Museum.

The aim and purpose of the founder are to render the collections of real educative value and to make them helpful to research workers, students and others interested in the history of medicine and allied sciences.

In the course of his introductory speech from the chair, Sir Humphry Rolleston said:—The study of medical history is somewhat paradoxically a modern development, and its expansion in this country has been largely due to Dr. J. F. Payne, Sir W. Osler, Sir Clifford Allbutt, and especially to Sir N. Moore, who, as President of the Section of the History of Medicine of the International Congress of Medicine in London, opened for the first time this Museum on June 24, 1913. Since then it has grown from strength to strength, and, after a complete re-organization, which necessitated its closure for eleven months, is virtually a new museum. This research museum is intended to be continually progressive, not to remain as the last word in 1926, but to keep up with the advance of medicine. In the various groups, such as anatomy, physiology, chemistry, pharmacology, orthopædics, obstetrics, psychiatry, massage and antiseptic surgery, it will show at a glance the evolution of ideas, discoveries and inventions in a really scientific manner. Thus, in addition to advances, it will elucidate the retrogressive changes which took place in some ancient eastern countries and in Europe during the dark ages.

Familiarity with what "famous men and our fathers who begat us" have done to build up our present state of knowledge has a great educational value. Further, it exerts a wholesome influence in making us feel modest from the realization of what our professional ancestors did in so much less favourable circumstances; we may indeed even find that discoveries made, or largely anticipated, by them years ago and long forgotten have independently again been brought to the light of modern eyes. It is salutary to look back and occasionally, as has been done with much advantage in the past, to act on the dictum "back to Hippocrates." The Great War carried the practice of surgery "back to Lister," the centenary of whose birth will be celebrated next year. Antiseptic surgery and anæsthetics are the two greatest milestones in the advance of surgery, and here is presented a collection of Listerian relics—unrivalled for its completeness; it includes part of Lister's ward in the Royal Infirmary, Glasgow, where he did his immortal work, which, had it not been for Mr. Wellcome's prompt action, would have been for ever lost when the building was demolished two years ago.

London is fortunate indeed in this unique museum, and the whole medical profession are under a deep debt to Mr. H. S. Wellcome for his unbounded generosity and enterprise in making and throwing open to us all this wealth of historical lore. It is indeed difficult to say what this museum, with its contents and a library of more than 100,000 books, manuscripts and incunabula so quietly amassed, will mean to medicine in the future. Its resources have always been most freely at the call of those interested and working at the subject.

Sir Arthur Keith, M.D., F.R.C.S., F.R.S., Conservator of the Museum, Royal College of Surgeons, England, gave an address on the history of medicine.

"England has a way of throwing up sporadic crops of great men; she had a bumper crop in the 19th century: Darwin, Galton, Taylor and Pitt-Rivers came along almost in a bunch—Darwin leading. It was Pitt-Rivers who demonstrated how reliable human history could be built up, bit by bit, in the shelves and show-cases of a museum; it was he who made the spade an instrument of exact history in the hands of a trained observer; it was he who pressed home the study of living primitive peoples as a clue to the customs, myths and beliefs of our long dead ancestors. What Pitt-Rivers did for human culture in general Mr. Wellcome has sought to do for a great branch of human knowledge—all that pertains to the art and science of healing. He has ransacked the world and brought together under one roof a rich, rare and vast assortment of materials for the history of medicine such as has never before been seen or studied in any country.

Now the evolution or history of medicine is more difficult than any other branch of knowledge to illustrate by museum methods. The trend of evolution is nearly always towards complication; if we trace the history of a man's fighting weapons, we begin with a few types of a simple kind and we end in these modern days with the innumerable and highly differentiated engines of war. But in medicine it is otherwise; even amongst the most primitive races of mankind, we find that the practice of medicine is founded on an elaborate code of belief; these beliefs are the fine-drawn gossamer of savage fancy—altogether too delicate threads for the clumsy fingers of museum curators to touch. If our task were merely to illustrate how the medicine man, whose image you will see to-night in his hut in New Guinea, seated amidst the simple and uncouth emblems of his art, becomes the fashionable physician of Harley Street with the artillery of modern science at his disposal, there would be no technical difficulty, for from the countries which lie between New Guinea and Harley Street we could cull a perfect series of ascending forms—an intermediate series of the kind which is so dear to the hearts of museum curators. Our difficulties begin when we seek to portray how the native practitioner looks upon the human body when it is well and when it is ill. Until we have surmounted this difficulty, we cannot appreciate the riches which are shown in Mr. Wellcome's "Hall of Primitive Medicine."

To give a concrete representation of the beliefs in which medicine begins is particularly hard for men like myself. We have been trained to accept only what we can see and prove, to suppress all our childish notions. We find it almost impossible to take the mentality of primitive medicine seriously. It would have been otherwise with Lewis Carroll, the immortal creator of "Alice in Wonderland"; he understood how children reasoned, and, therefore, could have entered the hearts of primitive men without effort. There can be no doubt that in the play of his fancy, early man, like the primitive races of to-day, was a child and had a childish way of reasoning. The late and gifted Dr. W. H. R. Rivers, in his enquiries into the theory and art of medicine among the natives of Melanesia, was able to lay aside the scientific armature of his mind and to adopt the point of view of the practitioners he encountered in primitive communities. He found that the rudest native practitioner had, like his counterpart of Harley Street, a definite theory of disease and that the means he adopted for its cure were a logical outcome of this theory. Had Lewis Carroll told a New Guinea medical man that after the material Cheshire cat had vanished its smile remained behind, the statement would have been accepted without the raising of an eyebrow. It must be a very long time ago since primitive man began to look on the human body as a mere husk and the spirit within it as the real person, for this way of interpreting the living body is almost universal among native peoples. On this belief the native physician bases his treatment of disease. If a man is to be free from illness his spirit must remain free, intact, uninjured. Illness, the native holds,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

springs from the spirit—not, as we believe, from the flesh. If the spirit be driven out of the body and forsakes it permanently, then death occurs. This is how the Melanesian explains death to himself and to his patients. Hence, a native practitioner's business is to discover in what way injury or damage has fallen on his patient's spirit, and, as these injuries are usually caused by other spirits or baneful influences, it is clear that a native, to practise successfully, must have studied and mastered the ways and wiles of these immaterial beings and things. The expert native practitioner is he who can best cajole the cloud of spirits which permeate the air of primitive communities.

As we dig into the beginnings of medicine, we find that its foundations are laid on leechcraft, witchcraft and priestcraft. The early physician was also magician and priest. Unless you have grasped this truth you will altogether fail to understand Mr. Wellcome's "Hall of Primitive Medicine"; for in that Hall you will find a wealth of amulets, charms, talismans, mascots, phylacteries, totems, fetishes, divination bowls, effigies, idols, masks and ceremonial dresses. When you examine the contents of that room you are really surveying a massed field of therapeutic artillery—the batteries by which ancient physicians sought to banish illness and disease from their patients, thus staving off death. The counterparts of the native artillery in Harley Street are the stethoscope, the bismuth meal, note-book for prescriptions, and a certain professional air.

The divination bowl, fetish, amulet, charm, mascot and effigy are but the symbols of the ancient practitioner's art; each is pregnant with significance; it needs a world of knowledge to interpret that significance. It is otherwise in all the modern departures of medicine. You will have an opportunity to-night of examining in this Museum all the stages in the evolution of utensils, apparatus and instruments employed in modern medicine and surgery; never before has the story of surgical instruments been told with such a wealth of illustration as will fall under your eyes here. The microscope is the main instrument of medical progress; this Museum contains its full history in the great collection shown in the Gallery. Never before have such pains been taken and so much wealth lavished to secure exact reproductions of the conditions amidst which druggist, chemist and apothecary carried out their respective callings in past times. You will see the actual ward from the old Infirmary of Glasgow in which Lord Lister banished from the world for ever some of the most dreaded of human sufferings. If you are inclined to think that the value of this exhibit is sentimental rather than useful, a glance at its bare ugly walls and its sordid equipment will alter your opinion. I was trained in just such a ward and know that the picture here preserved is true to its time. The men and women of a younger generation, who have grown up in clean bright wards with modern equipment can only realize the blessings which progress has brought them, when they view the ward in which Lord Lister's patients lay as he and his nurses ministered to their needs.

You will turn away from Lord Lister's ward devoutly thankful that it is now only a historical record; it depicts a state of matters which we have left behind us. It is possible, as you walk through the Hall of Primitive Medicine and your eye catches again the weird and uncouth equipments of native witch doctors which cover its walls and fill its cases; that you will view these exhibits as mere flotsam and jetsam from the Dead Sea of medicine—one which enlightened England has long since swept away. I should like to think this is so, but when I see, as I sometimes do, mascots on the motor cars of the wealthy, charms and amulets treasured by many people—both rich and poor—ignorant and educated; when I see, as I occasionally do, the quack preferred to the man who has given his life to the study of rational medicine; and when I see learned men call in spirits to explain unusual physical phenomena; then I am not quite so certain that this part of Mr. Wellcome's Museum does represent altogether a past stage of things. In all of us there still remains more than a trace of the primitive man.

Now I come to what is the main matter of my discourse. What is the service that such a museum as this should render to medicine? Let me put the question on a wider basis. What should museums do for us? You will pardon my immodesty if I refer for a moment to the services which museums have rendered to myself. Thirty-five years ago I returned from a sojourn in the East, where I had accumulated a great many facts relating to anatomy, and in my pocket just enough money to secure food and lodging for a year or two. My little cargo of anatomical facts was of no use in the world of learning until it had been compared with and added to cargoes brought home by previous voyagers into the realms of anatomy. It was my first duty to assimilate the publications of other workers and to study kindred material which had been gathered in our great Museums. The British Museum was thrown open to me; in its Reading Room attendants brought and laid before me books and manuscripts of all times and of all countries. The treasures in the Natural History Museum, South Kensington, were placed freely at my disposal. The Museum which I have now the honour to be closely connected with, served me as a study and as a research room. All of these institutions were provided for me gratis, free and for nothing. I never enquired into the cost of running these great institutions during the years I was using them, but I can tell you what all three cost last year. The British Museum, Bloomsbury, required £221,000; the Natural History Museum, South Kensington, £100,000; the Museum of the Royal College of Surgeons, the most economical and best Museum of its kind in the world, £6,000. Now that is a great sum of money. Museums, as Mr. Wellcome knows well, are very costly machines to run, to say nothing of the initial cost of bricks and mortar, and also outfit. To produce an income of £327,000, the sum now spent annually on these three institutions, needs a capital of about 6½ millions. You can see, then, that in those early days of study and research in London I was, although I did not realize it, terribly wealthy. I had the privileges of a Crœsus—a multi-millionaire. At least I had at my disposal that which had cost millions. It is plain that museums as instruments of research are very costly, and you may ask if the country is getting an adequate return for its great outlay. Well, if I had been the only student who then enjoyed museum benefits, our country would have had an altogether unsatisfactory return for its expenditure, but I was only one of many of that generation. The generation which was young thirty years ago is now providing their country with leaders and teachers, and England is reaping to-day the harvest she sowed in museums a generation ago. You see that I do not hesitate in regarding the increase of knowledge—the fostering of research—as the first duty of a museum. Unless a museum is permeated with a spirit of enquiry it is dead. It is not enough to furnish a museum with the materials needed by students; no conservator can understand what a student needs unless he is also a student. The staff of a museum must be permeated with the love of knowledge and know how it can be extended if their institution is to thrive; and no man can continue to be a student unless you give him an exit for his knowledge. Unless he is encouraged to coin his gold and pass it into circulation, his mint becomes choked. One knows that a museum is prospering when the members of its staff are participating in the proceedings of learned societies and contributing to their publications. One knows that a museum is fulfilling its primary function when its rooms and closets are frequented by research students from homelands, colonies and foreign countries, and one knows that its contents are being rightly used by the frequency of grateful acknowledgments in learned publications. The literature which issues from a museum determines its status, and in this literature I include catalogues.

If the first duty of a museum, such as this of Mr. Wellcome, is to serve the needs of students and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

through students the public weal, there is a second duty no less important. There is its immediate duty to the public—the duty of direct education. It is this double duty of a museum that taxes the ingenuity of us conservators. To expose the whole of our resources to the gaze of visitors would be to satiate—not to whet—their curiosity. We produce in them not only headache but mental dyspepsia. We have to select from our great stores on which special students regale themselves, just those prime pieces of instruction which when set in a right order, tell their story with emphasis and without words. Such an art needs a special genius, just as "window-dressing" does in the world of commerce, but I have noticed that the best elementary treatises are usually written by the most learned of our masters, and I am therefore hopeful that the most learned of our curators will also prove the greatest craftsmen in the art of "case-dressing." It is an art which makes a special appeal to Mr. Wellcome and he has surrounded himself with a staff of learned and expert men.

All of us who regard museums not only as repositories of valuable things, but as engines for the advancement of knowledge owe a debt to Mr. Wellcome. Students of history are usually poor men and this is particularly true of those who seek to unravel and write the true history of medicine. The materials needed for our studies are far beyond the resources of our purses. There are those men, who, setting out in their careers to banish care by obtaining a sufficiency to carry them and theirs to the end of life's journey, awake to find that wealth accumulates on them so fast that affluence becomes more burdensome than the cares of poverty. Well! we who benefit from museums are not in this group of men. If a poor man has to seek comfort in philosophy, a rich man, if he is to retain his soul, has to seek it as a necessity. The other day it was my good fortune to read a book written by a man who has become both a millionaire and a philosopher. "I have long felt and believed," he tells us, "that every man who has attained material success should look upon himself as an investment, so to speak, which the community has made. In return for the opportunities given to him and for the financial results they have brought, it is up to him to yield dividends in service and in other things of value to the community." Long before this philosophy for wealthy men had been formulated, Mr. Henry S. Wellcome, in his own quiet but efficient way, had begun to put it into practice. He had come to the rescue of us poor students and put at our disposal, and for the ultimate good of mankind, this Museum with its rich and rare stores of knowledge culled from all the countries of the world and from all periods of time. He has lifted our poverty above all dreams of avarice and has thereby earned the lasting gratitude of all who believe that the safety of our civilization lies in the progress and dissemination of knowledge."

Dangers Associated with Medical Practice and How to Avoid Them.

By W. E. HEMPSON,

Solicitor to the British Medical Association.

(*British Med. Journ.*, Aug. 21, 1926, p. 329.)

THE responsibilities which a medical man assumes appear to fall within three distinct categories—to himself and to his profession, to his patients, and to the State.

Mr. Hempson quoted with approval a leading article in the *Times* of March 4th, headed "Doctors and the Public."

"To contend....that the public interest can possibly be served by exempting anyone who is to enjoy the status of a registered medical practitioner, from training in those sciences by means of which alone a diagnosis of disease can be made, is on the face of it ridiculous. There can be no 'backdoor' to the *Medical Register*. Nor can the public suffer for a moment any depletion by doctors of their right to determine the nature of a patient's complaint."

Of late years there have sprung up many new cults, such as osteopathy, chiropractic, Abramsism, and Eddyism. Such lures as they may possess are to be avoided by the self-respecting practitioner as presenting features which may tend to imperil his good name and professional reputation.

Mr. Hempson uttered a warning against the practices of fee-sharing and accepting commissions.

The responsibilities of a medical man towards his patients, regarded from a legal standpoint, were aptly summarized by a learned judge in the following words:

"Every person who enters into a learned profession undertakes to bring to the exercise of it a reasonable degree of care and skill. He does not undertake, if he is a surgeon, that he will perform a cure, nor does he undertake to use the highest possible degree of skill. There may be persons who have higher education and greater advantages than he has, but he undertakes to bring a fair, reasonable and competent degree of skill, and the question which always arises is whether the injury must be referred to the want of a proper degree of skill and care in the person whose conduct is sought to be impeached."

The arrangement between a medical man and his patient has for its foundation and basis that of "*contract.*" The patient who retains the services of a medical man undertakes to pay his proper fees for treatment received, and the medical man undertakes to bring a due and proper meed of skill to bear and to treat the patient with every reasonable care.

The obligations of a medical man to the State arise under the head of criminal liability for negligence, and the following extracts from the dicta of learned judges will suffice to make the position clear in this respect.

"Where death is occasioned by negligence on the part of anyone professing to deal with the health of others whether he be a licensed practitioner or not the offence may, under certain circumstances, indicating a wanton and malicious disregard of human life, amount to murder. Of course a medical practitioner who should intentionally and with malice cause the death of a patient would be held guilty of this crime, but in no case will an indictment for murder lie unless there be a felonious destruction of life with malice either expressed or implied. The law holds, however, that every person, whether licensed or unlicensed, who deals with the life or health of any of His Majesty's subjects, is bound to have and to use competent skill, and sufficient attention, and that if the patient die for want of either the person is guilty of manslaughter."

The late Lord Ellenborough expressed himself as follows:—

"To make out a case of manslaughter, the prisoner must have been guilty of criminal misconduct arising either from the grossest ignorance or the most criminal inattention."

Of all professional men, the medical man is the one most popularly selected for speculative actions.

Nothing is easier than to attack a medical man on the ground that he has inaccurately or imperfectly diagnosed a particular case, or that, having correctly diagnosed it, he has improperly treated it, or, in the case of an injury by fractures or otherwise, that he has failed to appreciate the severity of the injury, or, having correctly diagnosed it, has failed to apply to it modern and skilled recognized surgery.

It is also to be found that little difficulty is experienced within the ranks of the medical profession itself in obtaining evidence whereby to give some support to the allegations of negligence or incompetence which are preferred.

In certain instances medical men in equal numbers have appeared in open court before judge and jury, of whom one half gave evidence in approval and the other half in condemnation of the treatment or diagnosis by one of their colleagues.

During one period of fifteen years, in which 2,467 cases were referred to Mr. Hempson by the Medical

A NOTE OF WARNING!

DOUBT having been expressed by a medical practitioner in a recent issue of the *B.M.J.* as to the efficiency of Dimol when taken in the form of pulverettes, we desire once more to call attention to the fact that, where there is a deficiency of pancreatic enzyme, all keratin-coated tablets or pulverettes are liable to pass undissolved throughout the intestinal tract.

For this reason, and at the suggestion of various correspondents, sugar-coated B Dimol pulverettes (yellow) have been prepared and are found to give most gratifying results. They are partially dissolved in their passage through the stomach, but the action of Dimol is not impaired thereby, and is free to exert its powerful influence immediately after its passage through the pylorus; whereas the keratin-coated A Dimol pulverettes (white), even under the most favourable conditions cannot be expected to get to work so quickly, and may even, as above explained, pass undissolved.

Each pulverette contains 1 gr. pure Dimol, and Dimol is guaranteed by the Rideal-Walker test to be 35 times more efficient as a bactericide than carbolic acid; that is to say, in administering 3 Dimol Pulverettes, the patient is receiving the bactericidal equivalent of 105 grains of carbolic acid. Moreover, it is not absorbed, being voided with the fæces after doing its work.

When we are able to repeat this dosage four or five times a day without affecting the appetite or digestion, and without action on the mucosa, we can readily understand the excellent results which are obtained by the administration of Dimol in the treatment of auto-intoxication due to intestinal putrefaction, non-amœbic dysentery, rheumatoid arthritis, acute and chronic colitis, acute gastro-enteritis and intestinal fermentation.

Defence Union, nearly 500 involved the defence of members of the profession in actions for damages founded upon allegations of want of care and skill in the treatment of their patients, and nearly 800 had relation to libel and slander actions either prosecuted or defended on behalf of medical men.

Mr. Hempson warned practitioners against failure to observe and act upon the danger signal which is ever present in these cases. Some complaint in regard to the account rendered, with a carefully veiled innuendo that the patient had not made satisfactory progress or recovery, is usually to be found as the starting-point, or alternatively a suggestion that if some other remedy than that prescribed had been resorted to, better results would have been obtained.

A communication of this nature is a prelude to trouble brewing. If there is doubt or difficulty as to the manner in which it should be dealt with, then advice on the subject should be sought through those channels of knowledge and experience which are open to you.

One further point must also be accentuated—namely, "beware of compromise." If your account for services rendered is impeached on the ground that you did not give value for money, your duty to yourself and to your profession is to enforce payment of it through the proper legal channels. If your patient, or his or her near relatives, impugn your treatment, insist upon a full and complete withdrawal of such allegations, and refuse to continue further to attend them if this be not forthcoming.

Mr. Hempson cited the following interesting case:—"A medical man was threatened with an action for damages arising out of his alleged unskilful treatment of a patient. Left to himself he would have settled it on any terms within the compass of his means as he dreaded the publicity which would follow upon its being heard in court. To this I absolutely refused to be a party. The solicitor acting for the claimant came and saw me, having travelled some 200 miles to do so. He opened with an offer to accept £100 and his costs, coming down by gradations to his travelling expenses to London, which I incontinently refused. He left much chagrined, and did not trouble me further."

Civil liability for neglect lies in the failure to exercise reasonable care and skill, whilst gross ignorance or criminal inattention are necessary incidents to support a charge of manslaughter, and a wanton and malicious disregard of human life in the treatment of a patient have been held to amount to murder.

Mr. Hempson strongly recommended medical men to join one of the defence societies immediately after they have registered. Outside this protection a man stands alone, never knowing when or in what circumstances his treatment of a case may be impeached, or the extent to which such an impeachment may be carried. The subscription to any one of these societies should be within the competence of all, and it is a species of insurance which no prudent man should neglect.

Bronchial Spirochætosis.

IN the *Revue Pratique Des Maladies Des Pays Chauds* for April 1826 Dr. Dopter has an interesting article on this condition. He regards it as a definite clinical entity which, though seldom infectious, may in some cases occur in epidemic form. He mentions an instance in which twenty-four persons were infected by a single patient.

Most of the cases begin with coryza and appear to behave like other acute infections of the respiratory passages, others take their origin from a Vincent's angina, others begin insidiously or with primary bronchitis.

General symptoms are usual, frontal headache, wasting, irregular fever, sometimes hæmaturia. There is usually abundant expectoration which may be blood stained, accompanied with cough. Five out of forty-two cases had hæmaturia, and in three of these cases spirochætes were found in the urine. There is sometimes an association with tuberculosis.

Stress is laid on the frequency with which the condition gives rise to a generalised spirochætosis, though in most cases the manifestations appear to be confined to the air passages.

Treatment with stovarsol in large doses gave remarkable results, even in cases which had proved refractory to prolonged treatment by other drugs. The doses employed were 0.75 to 1 gramme daily for fifteen to twenty days. The occurrence of diarrhœa and even jaundice is not regarded as a good reason for interrupting the treatment. In a few cases in which stovarsol failed, large doses of tincture of iodine (*French Codex*)—fifty to seventy drops by the mouth daily—gave excellent results.

Posture during Anæsthesia.

MR. W. MYEAR in the *American Journal of Surgery* for August 1926, lays stress on the importance of adopting the Trendelenberg posture both during and after anæsthesia.

This position is recommended not merely to avoid the dangers of aspirating material into the bronchial tubes, but also because it ensures a proper blood supply to the brain and so helps to prevent failure of the vasomotor mechanism.

Anæsthesia in Abdominal Surgery.

By Professor H. FINISTERER.

(*British Med. Journ.*, Aug. 14, 1926, p. 290.)

ANÆSTHESIA has become a highly specialized subject, as will be seen from the following brief extracts from a paper by Prof. H. Finisterer of Vienna at the meeting of the British Medical Association.

The work of Crile has revolutionized the methods of administering anæsthetics and the paper by Professor Finisterer may be regarded as a summary of the most modern methods of procedure which are in vogue in Europe and America.

It is to be feared that some of these are too complicated for every-day use in Indian practice but our readers will be interested to know what is being done in countries where extreme specialism is practicable.

Prof. Finisterer said that for many years he had practically employed only the regional and the combined methods. He refuses to operate on patients who insist upon a general anæsthetic.

The advantages of general narcosis are complete loss of consciousness, complete muscular relaxation, and the ability to examine the entire peritoneal cavity. Its unfavourable features are primary danger of the anæsthetic, fall in blood pressure, operative shock, damage to the brain, heart, kidney, adrenals, etc., and lung complications.

To eliminate the disadvantages of general narcosis chloroform or ether is replaced by nitrous oxide, which when properly used is practically without danger. Its disadvantages are that frequently there is not enough relaxation of the abdominal musculature. This, however, can be obtained simply and effectively by the injection of novocaine into the musculi recti. Ethylene mixed with 10 to 20 per cent. oxygen gives a deep narcosis with marked relaxation without any bad effects. Its only disadvantages are its inflammability and explosive character. Acetylene is equally efficacious. Its greatest disadvantages—inflammability and explosiveness—can be practically eliminated by caution and use of Gauss's "re-breather."

By Crile's method of anoci-association the sensory nerves are blocked by injection of novocaine, and unconsciousness is effected by using nitrous oxide. Combined anæsthesia has been adopted by many surgeons. Through careful anæsthesia of the peritoneum of the anterior abdominal wall the greater part of the narcotizing agent can be avoided. It is necessary to inject novocaine also into the mesentery. Nitrous oxide or narcylen may be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

used as a supplemental agent. Ethyl chloride has also been used as a supplement to local anæsthesia by different surgeons, but it is dangerous.

Regional Anæsthesia.—To make extensive laparotomies really painless it is necessary to anæsthetize the peritoneum of the posterior as well as the anterior abdominal wall. This can be achieved by paravertebral or spinal anæsthesia. The agent generally employed is novocaine, of which on an average 200 c.cm. of ½ per cent. solution is used. Tutocain is much more effective than novocaine, necessitating the use of only ⅛ to ⅛ per cent. solution. As a pre-operative measure the patients receive, one hour before operation, 0.02 gram pantopon, and then, a quarter of an hour before operation, 0.01 to 0.02 gram morphine with 0.00025 to 0.0005 gram atropine. It is necessary to have a complete anæsthesia of the anterior abdominal wall. In order to obtain this, besides the external injections on the lateral border of the rectus muscle, it is advisable to inject novocain after opening the abdomen from the inside as far laterally as possible into the properitoneal tissue.

Mesenteric anæsthesia is the simplest and least dangerous method of regional anæsthesia; it is satisfactory in all cases in which all pulling can be avoided. It is entirely satisfactory in cases of resection for a movable ulcer or cancer in ptotic stomach; but when the ulcer penetrates into the pancreas a supporting narcosis is necessary. Mesenteric anæsthesia should be used in every operation begun under general narcosis in order to decrease the operative shock (Pannett).

Paravertebral anæsthesia is of advantage only in operations in which injection on one side suffices—for example, in colon resection, cholecystectomy, etc. *In cases of doubtful diagnosis it is far better to infiltrate the anterior abdominal wall prior to incision, examine the abdomen under short ether or nitrous oxide narcosis, and continue the operation with mesenteric or splanchnic anæsthesia.*

Splanchnic anæsthesia after the method of Braun is almost without danger, and in about 90 per cent. of operations on the upper abdomen sufficient.

Parasacral anæsthesia, combined with blocking of the lumbar segment, is sufficient for radical operation for cancer of the rectum and for all gynæcological operations.

By the use of regional or combined anæsthesia the results of major abdominal operations are improved, because death from so-called operative shock, pneumonia, and atony of the bowel can be almost always avoided.

"The Post-Graduate Medical Journal."

THOSE of our readers who are proceeding to England may be interested in the Fellowship of Medicine and Post-Graduate Medical Association, whose headquarters are at No. 1, Wimpole Street, London, W. 1. The Fellowship provides post-graduate lectures; special courses in the various special branches of medicine and surgery at the London hospitals; and a general course at the 50 general and special hospitals affiliated to the institution. The minimum annual subscription is 10*s.* which admits the holder to certain special lectures and demonstrations, and includes a copy of the monthly *Post-Graduate Medical Journal,* which is the official journal of the Fellowship.

The journal itself is published at a subscription rate of 6*s.* annually. A recent number which has come to hand contains lectures by Dr. G. A. Sytherland on breathlessness and dyspnœa in children; by Mr. H. P. Winsbury White, F.R.C.S., on the diagnosis of urinary diseases in children; by Dr. S. Roodhouse Gloyne on the pathology of bronchiectasis; by Mr. Zachary Cope, M.S., on surgical cases in outpatient practice; by Sir Arbuthnot Lane on the importance of post-graduate training; together with reviews and editorial notes. The journal is full of interesting matter. Communications with regard to the journal or the Fellowship should be addressed to the Secretary (Miss M. Roy) at No. 1, Wimpole Street.

Proceedings of the Bombay Medical Council.

IN accordance with a resolution passed by the Bombay Medical Council at a meeting held on 20th September 1926, the following summary of its proceedings is published in the medical press for general information.

1. Mr. Joseph Michael Pereira, M.B., C.M. (Edin.), was called before the Council to answer a charge of issuing sick certificates in a case in which he had not been in personal attendance on the patient during the period covered by the certificates.

Mr. Pereira was cross examined and questioned personally and after deliberation on the previous correspondence and the personal explanation offered, the Council decided that Mr. Joseph Michael Pereira had been guilty of infamous conduct in a professional respect and directed the Registrar to erase his name from the Medical Register.

2. Mr. Purshottam Narotam Patel, a registered practitioner, was called before the Council, but stated that he was unable to appear in person or by a legal representative. The Council therefore considered the charge, namely, that he had been convicted by a First Class Magistrate of making a false statement and fabricating his register of patients to support this false statement. On appeal to the Sessions Judge, the conviction was upheld.

The Council decided that Mr. Purshotam Narotam Patel had been guilty of infamous conduct in a professional respect and directed the Registrar to erase his name from the Medical Register.

3. Mr. Dharamdas Kaushalyadas, an unqualified medical practitioner at Bulsar, submitted an application for recognition and registration. This was supported by certificates as to capacity for medical practice signed by Mr. B. M. Khambatta, L.M.S. and Mr. T. C. Khandwala, L.M.S. The Council decided that as the applicant had not had a training in any medical school, he cannot be registered.

Mr. Khambatta and Mr. Khandwala who issued the certificates submitted were warned that their action in associating themselves with an unqualified practitioner was highly irregular [*vide* Ethical Suggestions No. 1 (*e*)].

4. It was decided that the draft of a revised Code of Medical Ethics be circulated to the various medical societies in the Presidency for their opinion and remarks. This will be considered at a subsequent meeting of the Council.

5. An application from Dr. R. H. Bhadkamkar, M.D. (Bom.), whose name was erased from the Register on 17th February 1921, for restoration, was considered.

Dr. Bhadkamkar having given an unqualified assurance that he would sever all connection with Messrs. N. Powell & Co., where he had been acting as Director of their Laboratories, the Council, after due deliberation, decided to permit Dr. Bhadkamkar's name to be restored to the Register.

Reviews.

ATLAS OF THE HISTORY OF MEDICINE. I. ANATOMY.—By Dr. J. G. de Lint. London: H. K. Lewis & Co., Ltd., 1926. Pp. 96. Illustrations 199. Price, 15s. net.

THIS atlas is composed of a series of figures illustrating the history of anatomy and gives a picture of its development from the earliest times to the present day. The authors' aim is to aid the study of anatomy by awakening the memory of the past. They have produced the original drawings made by the anatomists of old days with their own hands whenever possible, and in other cases have reproduced their portraits obtained from title pages of books or other sources. Anatomy forms the basis of medical science. This book, we hope, will stimulate the interest of both students and medical

Schering

INSULIN-SCHERING

A dry preparation of permanent stability prepared according to the directions of the

TORONTO COMMITTEE

and under the control of the

GERMAN INSULIN COMMITTEE

It is standardised in conformity with the usual international unit.

The dry substance and the fluid for preparing the solution is contained in one and the same packing. After dissolution the potency of Insulin-Schering persists for about 3 months.

Insulin-Schering is supplied to the Medical Profession in bottles of 5 c. c. in 2 strengths as follows :

Packing A 100 *units in* 5 *c.c.*
Packing B 50 *units in* 5 *c.c.*

Samples and Literature on request from our Representative:

Mr. RICHARD SCHENK, 20-1, Lal Bazar Street, CALCUTTA, or from Messrs. T. M. THAKORE & Co., 24, Church Gate Street, BOMBAY.

A NEW DISCOVERY

The Serotherapeutic Treatment of

ANAEMIA and HEMORRHAGE

by

HEMOSTYL

of

Dr. ROUSSEL (Paris).

The active element is the **serum** and the **blood** taken entirely from horses prepared by preliminary bleeding in a state of active hematopoiesis.

The **ampoules** contain 10 c.c. of pure **hemopoietic serum** to be injected with a little water in cases of anæmia, and to be injected pure in case of hemorrhage.

The syrup contains nothing but hemopoietic blood in a syrupy medium most agreeable and very soluble and is to be used for anæmia, chlorosis, etc.

The treatment with **HEMOSTYL is the only physiological treatment** of anæmia and is far more efficacious than the old methods with iron, hemoglobin, etc., etc.

Prescribed by 90,000 doctors in England, France, Spain, Italy, Belgium, Central and South America, etc., etc.

In April, 1925, there were at the "Institut de Serotherapie Hemopoietique of Romainville, Paris," 800 horses used for the production of serum.

practitioners in this subject. It is admirably produced and published.

DISEASES OF THE SKIN.—By James H. Sequeira, M.D. (Lond.), F.R.C.P. (Lond.), F.R.C.S. (Eng.), Fourth Edition. London: J. & A. Churchill, 1927. Pp. 644, with 56 plates in colour and 309 text figures. Price, £2-2-0 net.

THE fourth edition of this well known book on "Diseases of the Skin" by Dr. James Sequeira, has been very much enlarged by numerous additions, particularly of those skin diseases which are found in the tropics. In this respect Dr. Sequeira's book is especially helpful to workers in the tropics and is free from a failing which is common in most of the textbooks on this subject, which are therefore of little use to practitioners in tropical climates.

The coloured illustrations are particularly good, and they number 56, which is very large for a book costing only two guineas. This textbook can be confidently recommended to any student who requires information on the subject of diseases of the skin.

There are two points which could be remedied in the next edition. The literature should be brought up to date, as many of the references on the different skin diseases are only given up to 1914. The section on the anatomy and physiology of the skin is poor, and is covered by 9 pages. The effect of the endocrines on the skin and the recent work of Krogh on its capillaries are not considered at all.

These are suggestions for improvement and are in no way intended to detract from emphasising the great value of the book, which contains a wealth of clinical experience, illustrating the different diseases of the skin.

H. W. A.

BRAIN AND HEART: LECTURES ON PHYSIOLOGY. —By G. Fano. Translated by H. Ingleby. Bombay: Oxford University Press and Constable & Co., 1926. Pp. xv plus 142. Price, 8s. 6d.

THIS book is a collection of lectures given by the author in the Universities of Barcelona and Madrid, and deals with the author's investigation of the broad questions concerned with the functions of the heart and brain. It therefore appeals not only to medical readers, but to others interested in the wider issues of physiology. The author gives an account of his scientific observations in the form of an autobiography and his object has been to investigate the nature of the heart rhythm and the inherent excitability of living matter. He considers that heart and brain are both symbolic of automatism and of the wilfulness of life. He says that living matter differs from dead matter in that it is organised by the 'will to live.' From his experiments on the hearts of frogs and tortoises he draws conclusions, not only regarding the function of these organs, but also speculations on the origin of life and the behaviour of man himself. The author is not only a scientist but also an artist, and as such he combines conjecture and speculation in the field of scientific investigation. He warns his readers however not to exaggerate the importance of theories. The book is a very interesting and philosophic treatise, and should be widely read by medical as well as laymen.

HANDBOOK OF DISEASES OF THE RECTUM.—By Louis J. Hirschman, M.D., F.A.C.S., Professor of Proctology, Detroit College of Medicine, etc. Fourth Edition. St Louis: The C. V. Mosby Co., 1926. Pp. 403, with 252 illustrations and 5 coloured plates. Price, $6.50.

THIS book was published in 1909, with the object of supplying the general practitioner with a short and handy account of the diagnosis of ano-rectal disease and well illustrated instructions for the performance of those operations which can be done under local anæsthesia. The subjects of cancer and all conditions of the rectum and anus requiring operation under general anæsthesia are deliberately excluded. The fact that the work has run through four editions is proof that it fulfilled a need and we consider that it deserves to be more widely known in this country. Hæmorrhoids, fistula and fissure are all very common in India, the sufferers dislike the idea of an operation under anæsthesia and dislike still more the idea of going into hospital, and yet surgeons in India almost invariably treat these conditions by operation under general anæsthesia. They can be dealt with under local anæsthesia in the consulting room, or involve a stay of only a day or two in hospital, and in the United States there is a considerable number of surgeons practising as specialists in proctology on these lines. The advantage to the patient is so obvious that the extension of this field is much to be desired.

The present work will be found to be a reliable guide to this branch of practice. The opening chapter on anatomy is scrappy and the account of the lymphatics of the rectum is not in accordance with modern work. The chapter on examination however is very complete, though we are surprised that the electrically illuminated proctoscope finds no mention. The account of methods of local anæsthesia is excellent and we are glad to see a special section on the limitations of the method and consideration of the classes of case for which it is not suitable.

The rest of the work deals with the various diseases of the rectum very adequately, bearing in mind the limited scope of the book. We note that the author has little use for the injection treatment of hæmorrhoids, which he regards as a clumsy and tedious method, likely to be abandoned, except for a small class of case, when the ease with which a neat ligature operation can be done under local anæsthesia is realised. Anal papillitis is a common disease, almost unrecognised except by specialists, which may cause distressing symptoms and is easily recognised and treated by anyone possessing the knowledge and a few simple instruments.

The last chapters deal with dysentery and are from the pen of Dr. J. L. Jelks. He writes an article more suitable for a medical than a surgical textbook and lets himself go to the length of 9 pages on the subject of flagellate dysentery. He is pessimistic as to the prospects of a case of amœbic dysentery ever being cured by emetine and he makes no mention of Deek's bismuth treatment. But he has a lot of useful advice about topical treatment with and without the sigmoidoscope and the uses of appendicostomy and cæcostomy, subjects of which we hear nothing out here nowadays, though there seems no good reason why as excellent results should not be obtained in India as are claimed in America and elsewhere. The illustrations are numerous and of a high standard, and we cordially recommend this book to practitioners and surgeons.

W. L. H.

A GUIDE TO ANATOMY: FOR STUDENTS OF MEDICAL GYMNASTICS, MASSAGE AND MEDICAL ELECTRICITY.—By E. D. Ewart. Second Edition. London: H. K. Lewis & Co., Ltd., 1926. Pp. 336 plus xiv. Illustrations 97, including 35 Plates, 4 coloured. Price, 12s. 6d. net.

WE are glad to note that Dr. Ewart's little book *A Guide to Anatomy* has reached its second edition. It is certainly an improvement on the first, as a good deal of new matter has been added. The book is admirably adapted for the use of candidates for examinations of the Chartered Society of Massage and Medical Gymnastics. The treatment of the subject-matter is brief, but at the same time clear and lucid all through, leaving out unnecessary details. The illustrations are well chosen and well adapted for the needs of those for whom the book is intended. The list of examination questions at the end will be found very useful.

EXPERIMENTAL PHARMACOLOGY.—By Dr. Hans H. Meyer and Dr. R. Gottlieb. Second Edition in English; translated by V. E. Henderson. London: J. B. Lippincott & Co. Pp. 656. Figures 87, partly in colours and 2 coloured plates. Price, 30s. net. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta, at Rs. 22-8 net.

THE seventh edition of this classical and interesting textbook in pharmacology which now appears has long

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

been awaited. This book deals with the subject in quite a different way to other books. Instead of grouping drugs according to their chemical composition or botanic groups, the author approaches the subject from the point of view of the physiology of organs and shows how these functions may be altered by administration of drugs. The importance of an understanding of the function of organs in pharmacology and in the selection of drugs for therapeutic purposes is fully brought out. The book is brought thoroughly up to date and should be read by all students of pharmacology as well as by all practising physicians.

R. N. C.

THE FUNDAMENTALS OF SCHOOL HEALTH.—By James Kerr, M.A., M.D., D.P.H. London: George Allen & Unwin, Ltd. Pp. 859. Price, 35s. net.

THIS is one of the most interesting books on health that we have read for some time. It covers much more ground than might be guessed from its title. It is a detailed and serious exposition of what education really is, how methods and progress in educative methods should be guided, modified and adapted by a consideration of the physiology and pathology of the developing child. The author has skilfully avoided saying anywhere "The child is father of the man," but the quotation might have been put at the head of every page. Education is of two kinds, the natural and the formal. Natural education is an education by living, whose results and effects are incomparably greater than any school education. Formal education will always be directed mainly to the conventions necessary for civilised life. The chapter on mental development gives a succinct account of present knowledge regarding the functions of the various parts of the nervous system in relation to consciousness of action and control of primary instincts so far as we understand these. The supra-granular layer of the brain cortex is the educatable part of the nervous system and the seat of high intelligence. The gradual acquirement of control of primary emotions and instincts in the growing child and adolescent is accompanied by progressive (and *pari passu*) myelination of the neurones of those parts of the brain whose functions comprise intricate association and inhibition; and a knowledge of the periods when such control may be expected and guided is essential to the serious teacher. To take a simple example, the nerve centres for fine movements of the fingers do not reach their maturity till about the middle of school life; attempts of a child to do writing at an early age result in excessive efforts at stimulation—efforts that overflow, causing facial muscles to twist, the tongue to be protruded, and other contortions. Effort to educate and put in action association and other centres which are not ready for full function may similarly result in emotional overflow, resulting in permanent damage to the higher nervous system. There are still many nerves in the human brain which do not become myelinated throughout life. What nervous possibilities in future races may these not represent? The author admires the English Public School type of education. Mainly it would appear in that it gives the young adult an idea of his place in the social commonwealth, teaches him sinkage of self, gives him control over his emotions, and helps him to face changes in environment with equanimity and fearlessness.

The scientific observations on nutrition, growth, physique, and heredity are recondite and complete. The chapter on tuberculosis reveals the author's views on the duties of the State towards this disease. "If tubercle is an infection purely and simply predisposed to by the debility of over-work and the want of vitality, due to bad housing, poor wages and caused by infection from other persons in the community, it is the duty of the community to come to the aid of the sufferers and relieve them fully and freely without assessment or charges." He thinks the present campaign against the tuberculous cow in England is exaggerated and misdirected zeal. The tubercular cow has attracted attention instead of the tubercular person.

In common with many, the author cites Freud almost as a Darwin of the mental world. His method of psychological analysis in searching for psychical trauma attempts to follow back to the start the tangle of clues behind an action, i.e., to the two great springs of action, self preservation, and race preservation; the ego and the sex instincts. In common with many others he deplores that Freud's discovery should be so overlaid with pseudo-science that its full value is likely to be more depreciated than realised at present. To sex education he devotes but a page—"For the regulation of society it is not instruction in sexual processes that is needed, but instruction in the conventions and manners of society regarding them." At no time should sexual things be treated as hidden or secret, but as an ordinary subject. The only reasonable way is to make knowledge on sexual matters accessible and available, so common that none can miss it—in textbooks, dictionaries, cyclopædias and reference books. Above all, there should on the one hand be no taboo on any of Nature's methods, and on the other hand no foolish sentimentality about the "beauty and sacredness" of sexual things.

The chapters on vision, hearing, ventilation, infectious diseases, aphasia, school cleansing and school sites and buildings are all first rate and embody the result of much experience and observation and wide reading. The book has a much wider appeal than merely to school medical officers—it will interest, stimulate and teach the educationalist and the general practitioner and, if they could but read and understand it, the everyday father and mother.

It is a quotable book and we finish with the following:—"Intelligence is one thing, morality another, and wisdom combines them both in a sound mentality."

A. D. S.

MESENTERIC VASCULAR OCCLUSION: SUPPLEMENTED BY AN APPENDIX OF 76 ORIGINAL CASES.—By A. J. Cokkinis, M.B., B.S. (Lond.), F.R.C.S. (Eng.). London: Bailliere Tindall & Cox, 1926. Figures in the text 5. Pp. xii plus 159. Price, 10s. 6d. net.

THIS little book is a thesis embodying the results of original research on a subject of considerable surgical interest and importance. The author has carried out some interesting experiments by injection and ligature to ascertain the results of blocking of the mesenteric vessels, and has collected and analysed the records of 76 hitherto unpublished cases. His analysis leads him to the conclusion that venous thrombosis is more common than arterial occlusion in the proportion of 75 per cent. to 25 per cent., figures which are in striking contrast to those given by other writers. Sepsis in the territory drained by the mesenteric vein was the commonest cause in this series. The pathology and symptomatology are exhaustively discussed, and it is pointed out that a definite diagnosis can be made in many cases, also that treatment by operation is not so hopeless if it is undertaken within the first few hours; an operative mortality of about 80 per cent. is depressing, but it must be remembered that the condition is invariably fatal if untreated.

This book should remain the last word on the subject for some time to come; it is founded entirely on actual records of cases and not on publications by other people and constitutes a valuable addition to our knowledge of an obscure subject.

W. L. H.

CORRIGENDUM.

IN our issue for November 1926, in our review of Professor Julius Stieglitz's *Chemistry and Recent Progress in Medicine*, the name of the publishers should be the Williams and Wilkins Co., New York, and not as shown. Messrs. Baillière, Tindall and Cox are the British Agents for the Williams and Wilkins Co.

SOME B.D.H. PRODUCTS

BOROCAINE

The ideal local anæsthetic for all minor operations where injections are required.

Borocaine is specially indicated for use in dentistry, and for the production of anæsthesia by the block method.

CAPROKOL
(Hexyl-Resorcinol)

The urinary antiseptic for oral administration. Indicated for the treatment of cystitis, B. coli, prostatitis, and other infections of the urinary tract.

" Many of the patients here reported had been treated with other forms of therapy without result, which made the success of hexyl-resorcinol the more satisfying."

Vide Journal American Medical Association, March 6th, 1926, page 668.

PITUITARY EXTRACT

A sterile solution of the active principle of the infundibular lobe of the pituitary gland.

As made originally, and as supplied to members of the medical profession, the strength of PITUITARY EXTRACT B.D.H. is that which has been adopted as the standard by the International Committee of the Health Section of the League of Nations.

BETA-BOROCAINE

The ideal local anæsthetic for the production of surface anæsthesia.

Beta-Borocaine gives perfect anæsthesia when used for operations on the eye. It is ideal also in nose and throat surgery, and in genito-urinary work.

CONTRAMINE

Prevents and ameliorates metallic intoxication of any origin. In early syphilis an injection should be given after the fourth or fifth injection of arsenobenzene. In recurrent and late syphilis two injections of Contramine should precede each course of arsenobenzene and mercury. Contramine is particularly useful in rheumatism, arthritis and fibrositis, whether caused by the gonococcus or by any other organism.

TETRAFORM

The purest form of Carbon Tetrachloride. It is guaranteed to be absolutely free from Carbon disulphide and other toxic sulphur compounds. Its use is indicated in the treatment of Hookworm disease.

Tetraform is issued specially for Medicinal purposes in 4 oz., 8 oz., and 16 oz. glass stoppered bottles.

Descriptive literature in reference to any of the above sent post free on application to one of our representatives resident in India,

More than a Laxative

AGAROL is the *original* Mineral Oil—Agar-Agar Emulsion, and has these special advantages: Perfectly homogenized and stable; pleasant taste without artificial flavouring; freedom from sugar, alkalies and alcohol; no contraindications; no oil leakage; no griping or pain; no nausea or gastric disturbances; not habit forming.

AMONG the newer remedies of proven worth there is hardly one that has won the favour and esteem of thorough-going, conservative medical men more surely and completely than

AGAROL

This is due to the physiological manner of its action and the remarkable dependability of its effects.

A brief consideration of the composition of Agarol—with its carefully balanced proportions of pure mineral oil, agar-agar and phenolphthalein — followed by a practical clinical test, will convince the most critical practitioner that here is no ordinary laxative that produces merely a single evacuation and then leaves the bowels more constipated than before, but a rational corrective that he can rely upon to give him the aid he seeks in restoring the physiological regularity of the bowels.

Annual Reports.

ANNUAL PUBLIC HEALTH REPORT OF THE CENTRAL PROVINCES AND BERAR FOR THE YEAR 1925. BY LIEUT.-COLONEL H. G. STILES-WEBB, D.P.H., D.T.M. & H. (CAMB.), I.M.S., OFFICIATING DIRECTOR OF PUBLIC HEALTH, CENTRAL PROVINCES, NAGPUR: GOVT. PRESS, 1926. PRICE RS. 4-10-0.

THIS is a report which shows steady progress in all directions, and records an unusually low death-rate.

"The favourable conditions of 1924 continued in the year under review. Although the monsoon was deficient in parts of Berar and the *kharif* crops were consequently affected, there was no lack of rain elsewhere and for the province as a whole, from the point of view of the public health, the year was a satisfactory one. The supply of food-grains was adequate and there were no large fluctuations in prices. There was a good demand for labour and the wages paid were good except that in the cotton districts the marked drop in cotton prices had its inevitable reaction on the prevailing labour rates. The climatic and economic conditions of the year are clearly reflected in the statistics. The death-rate, 27.27 per thousand of population as compared with 32.59 in 1924, was the lowest recorded since 1901. Infant mortality declined to 204.44 per thousand births from 234.94 in the previous year. The birth-rate fell to slightly below that of 1924, but it exceeded the average for the preceding five years by 3.36 and the year was undoubtedly the healthiest on record for many years.

The fact that no less than 10 infants out of every 50 born died during their first year of life indicates the immensity of the problem of infant mortality which awaits solution. It is significant also that throughout the province during the ages of 15 to 30 (i.e., the child-bearing age), the number of female deaths largely exceeded that of males, while for every other age the contrary is the case. Many municipal committees have engaged midwives or female Assistant Medical Officers and Baby Week Celebrations were organized by a number of local bodies. Such celebrations serve a useful purpose in arousing enthusiasm but, as is pointed out in many of the district reports, they will fail in their object unless they give rise to something more permanent, such as the formation, as has successfully been done at Nagpur, of Child Welfare Centres. The annual Baby Show should in fact ultimately become the means of reviewing and advertising the work done in the Welfare Centres during the preceding twelve months. The two Child Welfare Centres maintained by the Nagpur Municipal Committee with the assistance of a Government grant to meet half the expenditure, continued to increase in usefulness and popularity and one more centre was opened towards the end of the year under the auspices of the Red Cross Society. The number of cases visited at these centres has steadily increased from 860 in 1921 to 3,583 in the year under report and the lower mortality among visited cases is very noticeable. It is hoped that the time will not now be long before such centres are established in important towns throughout the province. Government have made a grant of Rs. 20,000 this year to the Red Cross Society for Child Welfare, and propose, subject to the vote of the Legislative Council, making annual grants in future to that society, as it will best be able to guide and foster the movement, at any rate in its early stages.

A number of district reports comment on the necessity for some control over local *dais* and proposals for enabling municipalities at their option to ensure their compulsory registration are now under the consideration of Government. The problem of child welfare, however, will not be solved by legislation and the promulgation of rules alone. It is the education of the people in regard to the elementary principles of hygiene and modern sanitary methods, and the overcoming of the deep-rooted distrust of innovations which conflict with firmly established habits of domestic life, which are of far greater importance, and these can only be achieved by the spread of education and by the local leaders of the people themselves, either as private individuals or as members of local bodies, taking an active and personal interest.

Fevers are again reported as the cause of over 50 per cent. of the deaths occurring during the year. Malaria was prevalent throughout the province, especially in the Chhindwara and Betul districts. Free issues of quinine were made in the poor tracts comprised by the Chhindwara *jagirs*, and the Seoni District Council arranged for its free issue to school children and indigent persons in the malarious tracts of that district. It is regrettable therefore to note that though the price of quinine has not been changed, the issues from the Nagpur Central Jail decreased by 25 per cent. approximately during the year. As was pointed out in last year's report, the possibility of making this prophylactic remedy available at cheaper rates in malarious area is worthy of the consideration of local bodies and it is satisfactory to note the action taken by the Seoni District Council. Small-pox was the only disease which accounted for an increase in deaths and the progressive rise in mortality from this disease since 1923 is rather ominous. In the Amraoti district alone the increase has been from 173 in 1924 to 1,062 in the year under review. Many of the district reports comment on the difficulties experienced by vaccinators outside towns and the urgent necessity for making vaccination compulsory in rural areas. Legislation is involved and the Government is considering the question. There was a decrease in the mortality from plague. Of the 5,223 deaths reported, 3,385 occurred in Berar and 1,230 in the Jubbulpore district. For the first time for many years the epidemic did not recur in the autumn in Jubbulpore town, and as this event coincided with the starting of a rat destruction campaign towards the end of the previous year the committee will doubtless be encouraged to pursue their efforts with renewed vigour. The experience of the Nagpur Municipal Committee over a series of years seems to warrant the conclusion that, if rat destruction cannot confer complete immunity, the possibility of a rapidly spreading epidemic is at any rate minimized. It is satisfactory to note that a number of municipal committees are taking an increased interest in this matter. Recurring grants-in-aid were made to three municipal committees during the year and other local bodies which are seriously tackling the question may expect to receive similar assistance. Too much emphasis cannot be laid on the fact that half-hearted measures are useless and the minimum standard to be aimed at is a proportion of 100 rats per annum per hundred of population. Since the close of the year, the rate of 50 rats annually per hundred of population has been fixed by Government as an absolute minimum standard and grants to local bodies will only be made subject to this standard being reached.

The number of epidemic dispensaries fell from 31 to 29 owing to the Wardha District Council having ceased to contribute to the maintenance of two dispensaries in that district. One dispensary was maintained by the Bilaspur District Council. The remaining 28 assistant medical officers visited 5,458 villages and treated 95,190 patients as compared with 4,511 villages visited and 60,093 patients treated during 1924. Eleven thousand two hundred and eighty-nine plague and 80 cholera inoculations were performed. In the absence of epidemics the dispensaries were engaged in health propaganda, the inspection of school children and the checking of vital statistics. The proper training of assistant medical officers for epidemic work must await the materialisation of the project for a public health institute for the province.

An appeal was made by His Excellency the Governor during the year on behalf of the Leprosy Relief Association. A provincial committee and district committees were formed and approximately two lakhs of rupees collected. Some of the district reports in tracts where this disease is prevalent express dissatisfaction with the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

steps taken to deal with the problem locally, in response to the funds so liberally collected in the previous year. The covering government resolution emphasises that it is in the interest of the province that research work at the Central Institute should be energetically prosecuted and that the major portion of the funds collected in all provinces should be allotted to this purpose, but would still like to see greater energy displayed in grappling with the disease in affected areas. The Deputy Commissioner, Amraoti, points out that as it is in the early stages of the disease that the effects of treatment are most marked and efficacious and that as people though not adverse to treatment, will not go long distances or stay at central asylums for long periods in order to receive it, it is imperative that as many local assistant medical officers as possible should receive training in leprosy at Calcutta and on their return administer that treatment at their dispensaries. The Governor in Council is considering the question of taking action along these lines, beginning with tracts like the Chhattisgarh division and the Amraoti district where the disease appears to be especially widespread.

The failure of many municipal committees to appreciate the importance of registration of vital statistics is the subject of adverse comment in the report. Grants amounting in all to Rs. 2,11,548 were made by Government to municipal committees for sanitary works. Municipal committees spent 39 per cent. of their total income on health purposes as compared with 34 per cent. during the previous year. The proportion is still low and a further increase of expenditure on measures connected with public health, the maintenance of which is the first duty of municipal committees, is overdue, but there has been some improvement in this respect during the year.

REPORT ON THE PUBLIC HEALTH ADMINISTRATION OF THE PUNJAB FOR 1925. BY LIEUT.-COL. W. H. C. FORSTER, D.P.H., I.M.S., DIRECTOR OF PUBLIC HEALTH, PUNJAB. LAHORE, SUPDT., GOVT. PRINTING, PUNJAB, 1926. PRICE RS. 2-2-0.

IN spite of unfavourable climatic conditions, the year 1925 was one of the healthiest recorded in the Punjab. Rainfall was in defect and food prices higher than in normal years; yet there was a complete absence of any great epidemic or of the prevalence of epidemic diseases on a large scale.

The estimated population for the year was 21,433,691 and—as usual—the Punjab returned a high birth-rate 38.4 per mille on the estimated population. Epidemic disease in the Punjab is especially affected by climatic conditions, and a rainfall distribution favourable to plague and malaria is sufficient to cause soaring of the death-rate. In 1925, the critical December-May rainfall was unfavourable to plague with correspondingly favourable results. The distribution of the rainfall was also unfavourable to malaria, with a consequent drop in the fever death-rate as compared with the previous year.

The male birth-rate exceeded that of females, 111.9 males being born as against 100 females. The Punjab has the second highest birth-rate in India, being only surpassed by the Central Provinces. In Lahore town, the birth-rate shewed a falling off, due to the incidence of plague amongst women of child-bearing age. The excess of births over deaths stood at 10.1 per mille of the census population, as compared with a deficit of 3.3 in the previous year. These figures alone emphasise the dependence of the health of the Punjab on climatic conditions, and the general virility of its peoples in the absence of any severe epidemic; also the inherent powers of recovery of the Province after severe epidemics. The death-rate, 30.0 per mille, was not only 13.4 per mille less than that for the previous year, but also less than that for the previous quinquennium. Infant mortality dropped from 209.6 per mille in 1924 to 185.1 per mille in 1925, but still constituted one-quarter of the total mortality in the Province. The system of registration of births and deaths by *patwaris* instead of by *chaukidars* in rural areas, tentatively introduced in the districts of the Lahore division, was in operation throughout the year. The final reports on this system shew that the *thanewar* system of reporting vital statistics of rural areas is on the whole easier to work, cheaper, and not less accurate than the *patwari* system. Hence a return to the older system has been ordered.

Turning to the chief diseases, cholera assumed epidemic proportions of moderate severity during the year, accounted for 3,049 deaths as against 3,351 in the previous year, and a mortality of 0.15 per mille. The disease prevailed in 23 out of the 29 districts in the Province and Shahpur, Jhelum and Gurgaon were chiefly attacked. The disease appeared first in April and was definitely traced to importation of infection at the Katas fair in the Jhelum district. Within the short space of 10 days no less than 11 districts had become infected. This infection lingered on till June, when a fresh infection was imported from the United Provinces into the extreme south-east of the Punjab and was prevalent there until the end of October. The water supply arrangements at the Katas fair are primitive, the district board incapable of financing a proper water-supply, and roadside sources of water open to the greatest pollution. Arrangements had been made by the Public Health Department to cope with the sanitary needs of 15,000 people at the fair, but 50,000 attended it and the arrangements broke down. "Our fairs are a chronic danger and will remain so until the general sanitation of fair grounds is placed under some central and competent authority" writes Colonel Forster; "district boards and other local authorities are financially and administratively incapable of dealing with the matter."

Small-pox shewed an increase of 7,038 deaths as compared with 4,040 in 1924. The maximum mortality occurred in June with a secondary rise in the curve of incidence in December. There is now a large unprotected and susceptible population in the Punjab, largely as the result of the application of political theories. Extra staff was employed, and vigorous propaganda instituted. "Although the number of cases of small-pox is on the increase" runs the covering Government resolution to the report, "no local body except the municipal committees of Lahore, Amritsar and Simla have opened small-pox hospitals. Simla is the only place where a real effort is made to isolate cases of small-pox. Vigorous efforts are being made by the Public Health Department to make vaccination popular in the absence of statutory provisions requiring the compulsory vaccination of persons."

Plague during 1925 was "comparatively speaking, a very mild affair"; and the plague death-rate in British districts 1.83 per mille as against 12.24 in the previous year and a quinquennial average of 3.10 for the previous 5 years. The disease in 1925 was more prevalent in urban than in rural areas—a contrast to the experience of previous years. Pneumonic outbreaks were reported from Hissar, Rohtak, Lahore, Amritsar, Gujrat, and Attock. The mortality was at its maximum in April. All the usual anti-plague measures were taken, together with intensive measures in carry-over centres during the quiescent period. Inoculations numbered 304,981 during the year—a very satisfactory figure considering the mildness of the year's outbreak; whilst no less than 4,020 lantern lectures on the subject were delivered. It is clear that the population of the Punjab has come to appreciate the value of anti-plague measures.

Fevers as usual caused the greatest mortality—22.04 per mille. The greatest number of deaths was registered under this heading in September. Energetic measures in the Gurgaon district under Mr. F. L. Brayne, the Deputy Commissioner, have been eminently successful, with the result that this district scarcely figures at all in the list of fever mortality rates. Influenza was unimportant during the year, but relapsing fever still lingers in the western districts of the Province. Respiratory diseases accounted for a mortality of 2.65 per mille of the population, and Colonel Forster considers that tuberculosis in the Province is but part of the

Not only Vitamins

BUT —

While Virol has been definitely proved to contain the vitamins, it does not, like so many foods, found its claim to the attention of the Medical and Nursing Professions merely upon its vitamin content. The presence of vitamins is a minimum, not a maximum requirement.

Correct Balance

In Virol the relative proportions of Protein, Fat, Carbohydrate and Mineral Salts are carefully adjusted, thus providing the ideal diet for growth. For it has been shown that there is an interaction of the various food elements, and their effective influence on growth is dependent on their correct balance.

Perfect Digestibility

Many concentrated foods are either tolerated with difficulty by the stomach or, when digested, throw an undue strain upon the organs. In Virol neither of these defects is present; the fat is presented in the form of a highly digestible emulsion, and the proportion of protein is not so high as to give rise to derangement of nitro genous metabolism.

It is for these reasons that

VIROL

is used in over 3,000 Hospitals and Welfare Centres

given to prisoners to behave well will produce good results. Incidentally the release of these well behaved prisoners, most of whom were convict officers, has increased the need for more warders.

Useful work has again been done by the Boards of Visitors, especially in drawing the attention of the Inspector-General of Prisons and Government to the needs of their jails. There has, however, been a decrease in the number of individual visits by both official and non-official visitors.

It is a matter for regret that some jails are still without religious instruction. A difficulty in the way of securing honorary teachers has been removed by the provision of a grant for conveyance allowances, and it is hoped that it will now be possible to find such teachers for every jail.

There was a fall in the average earnings of prisoners sentenced to labour from Rs. 74-10 in 1924 to Rs. 67-13. The percentage of prisoners employed in manufactures was slightly higher in 1925 than in 1924, although it was still disappointingly low.

The best manufacturing work appears to have been done at the Dacca Central Jail where the woollen factory has been successful.

Correspondence.

SUSPENDED ANIMATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I was recently with a friend of mine, when a discussion arose as to how long breathing could be suspended. He told me that he could voluntarily suspend his breathing for twenty-five minutes and asked me to test him. I had no watch with me at the time, but I think that for at least ten minutes he was able to voluntarily suspend his breathing. He then stated that he could also control his heart beat. I placed my fingers on his pulse, and the pulse became gradually weaker and weaker, whilst his face began to change in colour, and assumed a death-like facies. Ultimately the pulse was almost imperceptible. I was fully satisfied as to his ability to control his heart beat voluntarily, and got somewhat nervous and asked him to stop the experiment. He wrote on a bit of paper near him "I am not dead, I am in *samadhi*. Don't burn my body. I shall come round."

Breathing exercises are highly spoken of as a general tonic and curative in some diseases, but practice in them should be gradual and the nose should not be held by the hand. This science is known as "pranvidya" by the Ayurveds; and the control of the breathing should be by the will and not forcibly by physical means. Can any of your readers give me further information on the subject? One knows quite well that such practices are in vogue amongst Indian mystics and others; but it would be interesting to learn details as to the powers of what one may term "voluntary catalepsy."—Yours, etc.,

RUDRA DUTT, L.M.S.,
Assistant Surgeon.

CIVIL HOSPITAL,
MAILSI, PUNJAB.
14th November, 1926.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Lieutenant-Colonel J. W. Watson, C.I.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Civil Surgeon, Ajmer and Chief Medical Officer in Rajputana, with effect from the 17th November 1926.

Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., Civil Surgeon, Simla, West, is appointed to hold charge of the duties of the Civil Surgeon, Simla, East, in addition to his own, during the absence on leave of Lieutenant-Colonel Macmillan.

Lieutenant-Colonel T. C. McCombie Young, M.D., I.M.S., is placed on foreign service under the Indian Research Fund Association with effect from the date on which he assumes charges of his duties.

The services of Major K. R. Batra, I.M.S., are placed temporarily at the disposal of the Government of the Punjab with effect from the date he assumes charge of his duties.

Major K. S. Thakur, I.M.S., is appointed to act as Civil Surgeon and is posted to Bakarganj.

Major P. F. Gow, D.S.O., M.B., I.M.S., is appointed to act as Second Professor of Midwifery and Gynæcology, Medical College, Calcutta, with effect from the afternoon of the 6th November 1926.

Captain R. M. Kharegat, I.M.S., an Officiating Agency Surgeon, is appointed to be additional Civil Surgeon, Ajmer, with effect from the 17th November 1926.

Captain J. C. Chakravarty, I.M.S., Resident Physician, Medical College Hospitals, Calcutta, is appointed to act in addition to his own duties, as Resident Surgeon, Medical College Hospitals, during the absence on leave of Major P. C. Banerji, I.M.S.

Captain J. C. Chakravarty, M.B., I.M.S., is placed on general duty at the Medical College Hospitals, Calcutta, with effect from the forenoon of the 13th November 1926.

LEAVE.

In modification of Education, Health and Lands Department Notification No. 1472-Health, dated 25th October 1926, Colonel A. W. R. Cochrane, M.B., F.R.C.S., I.M.S., Inspector-General of Civil Hospitals, United Provinces, is granted leave on average pay for 5 months and 28 days combined with leave on half average pay for 1 year 10 months and 2 days with effect from the 9th October 1926.

Lieutenant-Colonel A. C. MacGilchrist, I.M.S., Professor of Physiology, Medical College, Calcutta, is granted leave on average pay for three and a half months, under rule 81 (*b*) (*i*) of the Fundamental Rules, with effect from the 15th December 1926, or from any subsequent date on which he may avail himself of it.

Lieutenant-Colonel J. M. A. Macmillan, M.D., F.R.C.S., I.M.S., Civil Surgeon, Simla, East, is granted leave on average pay for one month and a half with effect from the 20th December 1926 or subsequent date on which he may avail himself of it.

Major E. W. O'G. Kirwan, F.R.C.S.I., I.M.S., Officiating Civil Surgeon, Mymensingh, is granted leave on average pay for four months, with effect from the 3rd January 1927.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

Lieutenant-Colonel G. Tate, M.B., V.H.S., *vice* Colonel A. W. R. Cochrane, M.B., F.R.C.S., dated 9th November 1926.

Major to be Lieutenant-Colonel.

William Cowan Gray, M.B. Dated 1st March 1925.

The promotion of Major F. Griffith, M.B., notified in Army Department Notification No. 1253, dated the 1st October 1926 is antedated from the 8th September 1926 to 8th March 1926.

Captains to be Majors.

Bindeshwari Prasad, M.B. Dated 2nd December 1926.
John Marsters Mitchell, O.B.E., M.B. Dated 13th December 1926.
Codanda Madiah Ganapathy, M.C., M.B. Dated 14th December 1926.
Nariman Jamshedji Gai, M.B. Dated 20th December 1926.
B. Z. Shah. Dated 5th November 1926.
A. J. D'Souza, M.C. Dated 5th November 1926.
R. H. Malone, M.D. Dated 6th November 1926.
V. N. Agate, M.B. Dated 11th November 1926.
J. P. Canteenwalla. Dated 15th November 1926.

Diarrhœa in Infancy

". . . the decline in deaths from infantile diarrhœa . . is due to the ever-increasing use of dried milk in infant feeding." *(Proceedings of National Milk Conference, p.196).*

Bacteria carried by the common house fly are the most prevalent cause in India.

Bacteria multiply in wet milk, but their growth is actually inhibited by waterless milk.

Prescribe Glaxo and prevent infantile diarrhœa.

ANABOLIN

(Tabs. Hepatic Extract Harrower)

—an active depressor principle
separated from the liver by fractional solvent methods—reduces
hypertension—per os,
Three tablets t.i.d. for
five days will prove its value.
This statement is backed up by
hundreds of clinical experiences
in cases of

HYPERPIESIS

Note: Anabolin is obtainable
also in boxes of six 1-cc. ampoules,
for intramuscular injection. It
is an advantage to start treatment
with the solution, later changing
to the oral method. The solution
lowers the blood-pressure rapidly
in most cases, and the tablets
may be relied upon to maintain
the lowered pressure.

NOTES.

MESSRS. ALLEN AND HANBURYS.

A REPRESENTATIVE of Allen & Hanburys, Mr. B. W. Clark, is making a prolonged visit to India for the purpose of displaying to hospitals and surgeons generally the company's productions in the way of surgical instruments and also to study local conditions. It is not generally known that this well known house manufactures instruments and apparatus of the finest quality and of the latest and most up-to-date patterns. The representative who will be in India for some years will tour the whole of the country gradually and will be visiting the principal cities in India, starting from Bombay and Karachi and then visiting the North and North-West previous to going South.

Any medical men interested should write to Allen & Hanburys, Ltd., Block "E," Clive Buildings, Calcutta.

INDEX OF THERAPEUTICS AND MATERIA MEDICA.

(Issued by the Bombay Branch of Parke Davis and Co. 1927.)

THIS most handy little volume is issued free to medical men upon request from Messrs. Parke Davis and Co., P. O. Box 88, and Lloyd Building, Bombay; also to the dental and veterinary professions. Those asking for it, however, should be careful to add their professional qualifications. In addition to much useful information on treatment, dosage, diets, incompatibles, weights and measures and biological products such as sera, vaccines, phylacogens, tuberculins, etc., and appliances, it contains a full list of the high grade drugs, hypodermic syringes, etc., issued by the firm. It is also most interestingly illustrated.

WATSON AND SONS' CATALOGUE OF MICROSCOPES.

MESSRS. W. WATSON AND SONS, 313, High Holborn, London, W. C. 1, have recently issued a new edition—the 31st—of their catalogue of microscopes and accessories. The catalogue is a most fascinating one to look through, and will appeal to every type of reader, both to the student in search of a cheap but reliable microscope, where the "Service" microscope is hard to beat, and to the research worker, who will find such models described as the magnificent grand model "Van Heurck" microscope, with every conceivable fitting, apparatus for the use of ultra-violet light in micro-photography; and the new, wonderful Chambers' microscope dissecting apparatus, with which all objectives up to the 1/12th in. oil immersion may be used, and with which the nucleus of a cell may be cut out, or a single bacillus or protozoon isolated. The catalogue is one of the completest and most interesting that we have seen for many years, and contains much scattered useful information as to choice of objectives and eyepieces, apochromats, etc. One special feature of many or most of Watson and Sons' microscopes is that the substage condenser possesses centering screws, and every worker of experience will know how much that adds to the efficiency of a microscope.

In addition there is included in the catalogue a list of second-hand microscopes and accessories available; also a copy of the issue of their *Microscope Record* for September, 1926, which contains a very interesting article by Mr. W. B. Stokes, formerly for many years Honorary Secretary of the Quekett Club, on the resolving power of the microscope, and a most thoughtful article by Mr. A. Coper on microscope construction. This journal is issued to laboratory workers upon application, and is always most informative and useful.

Perhaps one of the most interesting bits of apparatus manufactured by Messrs. Watson and Sons is their "Cassegrain" dark ground illuminator, one of the finest dark ground apparatuses ever designed, and suitable for use with any objective from 8 mm. to 2 mm. of 1.4 N.A., without any funnel stop or special illuminant. It is issued at £3-17-6, also with a special mount at £1-15-0 which provides centering screws.

Both the catalogue and the *Microscope Record* are worthy of a firm which is the largest and one of the best known firms of microscope makers in the Great Britain.

OGILVY'S CATALOGUE OF MICROSCOPICAL ILLUMINATING APPARATUS.

THOSE who had the pleasure of listening some 16 months ago or so to a lecture delivered in Calcutta by Mr. Ogilvy, will not soon forget the wonderful display which he gave at that lecture of different types of illuminating apparatus for the microscope, or of the fascinating suggestions which he made as to future developments in microscope construction. Hence it is with special pleasure that we welcome the issue by Ogilvy and Co., 20, Mortimer Street, London, W. 1, of a new catalogue of microscopical illuminating apparatus. The firm are themselves makers of microscopes and microscopic accessories, and also are the British agents for Leitz and Co.

The experienced microscope worker—even in the tropics—always comes in the long run to rely upon artificial illumination in preference to daylight, and there is no question that it enables one to see far more detail. For protozoological work it is almost essential. In this catalogue will be found lamps suitable for every type of worker, all of them designed for the electric current. For the student and for routine work the model No. 03 vertical lamp should prove most suitable, and costs £2-2-0 only; whilst a much higher class lamp with a condensing system and light filters, suitable for research work, is listed at £15-15-0. The Hartridge-Williams axial illuminator is an ideal illuminant; it is slipped into place instead of the microscope mirror, and gives truly axial, centered, illumination, the intensity of which can be adjusted to any extent by an iris diaphragm in the lamp. This makes the microscope at once self-contained; it can be used anywhere at any time and either in the vertical or the tilted position. Projection and "Pointolite" lamps are also fully described; whilst another most ingenious novelty is the "Silverman illuminator." This is an illuminating apparatus to fit around the objective of the microscope and throws light downwards on to a solid object. Mercury vapour lamps for ultra-violet rays, etc., are also described, and an admirable simple pattern of micro-projection apparatus which is similar to a pattern which the reviewer has been using for years and has found to be most satisfactory. In this the microscope is set horizontally, a beam from a special projection lamp is passed through the condenser, and slide, and reflected by a mirror fitted to the eyepiece of the microscope on to a flat drawing surface. With a folding screen, one can easily use the oil immersion lens with this outfit; and its advantage to professors and teachers who have to prepare histological or pathological diagrams, etc., for classes is very great. The outlines of the structures within the microscope field can be traced straight away, and if very fine detail is wanted, the microscope can then be set tilted, and the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

detail studied by the eye and filled in on the sketch. This apparatus is one which we would like especially to bring to the notice of teachers of histology and pathology.

The whole catalogue is one which will deeply interest laboratory workers, whilst the admirable workmanship of the firm ensures that their lamps are absolutely reliable. We have had two Ogilvy lamps in use for more than two years now, and have not even required to renew a bulb.

KINAZYME, CARNICK AND CO.

AN interesting new preparation is Kinazyme, prepared by Carnick and Co., the well-known manufacturers of glandular and endocrine products. This is a combination of gland substance—spleen, pancreas, pituitary, and parathyroid—and it is claimed that it is of special value in the treatment of tuberculosis and other wasting diseases. The oral administration of spleen substance increases the number of red blood corpuscles; pancreas substance is used to improve digestion; pituitary substance may give a slight impetus to general metabolism; whilst parathyroid substance has definitely been established as the chief factor in maintaining the normal level of the calcium content of the blood. Hence there may be a very wide range of tropical diseases where such a preparation may prove useful; chronic malaria, chronic dysentery, sprue, the anæmias and cachexias of the tropics, and tropical neurasthenia. The importance of studying endocrine functions in tropical diseases has hardly yet been sufficiently realised by the medical profession in the tropics, but there is already accumulating evidence that endocrine deficiency may be a most important factor in connection with many of the more chronic forms of tropical disease.

SCHERING'S PREPARATIONS.

SCHERING'S medical preparations are so well known in India that they call for little comment; but three of them may perhaps be especially noted on. The first is "Insulin-Schering." Doubts have been thrown upon the keeping properties of insulin in the tropics, and this preparation is put up in the most ingenious containers. It is a white powder, prepared according to the directions of the Toronto Committee, under the control of the German Insulin Committee, and standardised in accordance with the usual international unit. Such a dried preparation will keep indefinitely. The powder is contained in a little tube which is placed inside the rubber cap of a sterile phial containing sterile water. When it is wanted for use, pressure on the outer surface of the rubber cap drives the small tube into the fluid, where it dissolves, and the insulin solution is then ready for use, and can be aspirated into the syringe, just as is a vaccine from a rubber capped container. In this way, the insulin is kept dry and potent under tropical conditions until the moment when it is wanted for use. This novel method of putting up a drug liable to deterioration under tropical conditions is one of the most ingenious which we have seen, and we should like to see its use extended, e.g., to digitalis and other such preparations.

"Veramon-Schering" is a combination of analgesic drugs, the action of each of which reinforces that of the other by acting on different cerebral levels. It has been before the medical profession for three years, and reports by surgeons, dentists, ophthalmologists, and others speak of its value, its freedom from toxicity, and from habit-formation. It has also been largely used for the relief of dysmennorrhœa. The dose is 6 to 12 grains (one or two tablets). A minor, but useful, field of therapy is its administration before a minor dental operation such as an extraction or a filling, when it will quieten the patient and relieved nervousness.

"Krysolgan-Schering" is a gold preparation for intravenous administration in tuberculosis of all forms. It is the sodium salt of amino-auro-thio-phenol-carbonic acid, and characterised chemically by a very firm combination of the gold in the benzol nucleus, so that in aqueous solution it fails to give the ordinary reactions of the gold ion. The dose is from 0.01 gramme to 0.1 gramme, dissolved in sterile distilled water and given intravenously; starting with a very minute dose, the injections are given every 8 to 20 days until the patient has been worked up to 0.1 gramme or less. Earlier workers reported that the action of Krysolgan was like that of tuberculin, and tried to obtain a positive febrile reaction; but later ones report that it is better to avoid febrile reactions and to keep the dosage low, especially in pulmonary tuberculosis. Koch was the first, we believe, to advocate gold therapy in tuberculosis, whilst Feldt and Speiss investigated its action further. Kolbmann and Wiesner report on 180 case of phthisis treated for three months or more with Krysolgan, of whom they considered 103 to have received distinct benefit, whilst Schneider of Coblenz treated 40 cases of whom 14 were markedly improved. We are only probably at the commencement of the study of the possible role of colloidal solutions of the heavy metals in tubercular and allied infections, but Krysolgan appears to be an interesting compound. Many of those who have used it note especially that it has no toxic action on the kidneys.

The Indian agent for Schering's preparations is Richard Schenk, 20-1, Lal Bazar Street, Calcutta.

RUSSIAN SANTONIN.

IN our comment on p. 580 of our issue for November, 1926, on Russian santonin, we gave Messrs. Turnbull Bros. of Calcutta as the Indian agents for the Eastern and Russian Trading Co., manufacturers of santonin. We are now asked to state that Messrs. Turnbull Bros. are the agents for Calcutta, whilst Messrs. G. S. Mahommed, 164, Samual Street, Bombay, are the agents for Bombay.

MELLIN'S FOOD 1927 CALENDAR.

WE have received—unfortunately too late for notice in our issue for January 1927—a copy of Mellin's Food calendar for 1927. This shows a very charming baby, with the legend "Who said Mellin's Food ?" and is an attractive ornament for the desk or consulting room. The Indian agents are Messrs. Mackenzie Lyall and Co., 5, Mission Row, Calcutta; who will be glad to issue copies of the calendar gratis to the first five hundred applicants mentioning this journal.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c|o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

INTRACAPSULAR EXTRACTION OF CATARACT, INCLUDING THE MOST RECENT ADVANCES.*

By HENRY SMITH, C.I.E.,

LIEUT.-COLONEL, I.M.S. (Retired).

(*Note.*—The illustrations to this article have been taken from an article by the same author in Knapp's *Archives of Ophthalmology*, Vol. IV, No. 3, 1926, to which journal full acknowledgments are due.—ED., *I. M. G.*)

IN opening a discussion on this subject we have to touch on a variety of grounds which is before the profession to-day and is likely to be so for some time to come. I do not propose to touch on Pagenstecker and on those who preceded him. Their procedures are as dead as if they had never been. They are not likely to be resurrected. They are but of historic interest. They merely shew that intracapsular extraction has been the ambition of all surgeons since cataract extraction commenced.

Two methods hold the field—expression from without, and *expression* or extraction from within the eye. Expression from without in point of time takes precedence: it has been developed from the very beginning by the Indian Medical Service. Macnamara of Calcutta commenced it in 1864. He describes his method in the three editions of his book—1st edition, 1868, and 3rd edition 1884—as follows:—

"The object we have in view in this proceeding is to remove the lens without opening its capsule. The advantages it offers are that no capsular cataract can possibly form, and there is no chance of any soft lenticular matter being left clinging to the iris and setting up irritation and inflammation in that delicate structure.

"Atropine having been applied so as fully to dilate the pupil, the patient is to be laid on his back and chloroform administered: (there was no cocaine in those days). The surgeon standing by the side of his patient applies the stop speculum; and the eye being fixed with a pair of forceps, a flap is to be made through the lower section of the sclerotic immediately beyond the margin of the cornea, the same precautions being taken as I have already described in the case of ordinary flap extraction. A portion of the lower part of the iris is then to be excised, and gentle pressure exercised with the curette upon the lower part of the sclerotic and at the same time pressure is to be made with the point of the finger upon the upper part of the eyeball. In this way the lens in its capsule may be forced out of the eye. If the lens is not rapidly displaced upon slight pressure being made upon the globe of the eye, the curette may be inserted behind it and a gentle traction exerted on the lens so as to start it from its position.

"In making the flap we must keep slightly external to the margin of the cornea, so as to leave as large an opening as possible through which the lens may escape, its bulk when contained within the capsule being considerable.

"This operation is no doubt a very valuable one and often leads to most favourable results. Even though there is a difficulty in extraction of the lens in its capsule the latter may be opened, and the operation completed as an ordinary flap extraction: in fact, it will be always advisable to resort to this proceeding unless the lens and capsule are forced through the section in the cornea upon slight pressure being made on the eyeball: any extra force is likely to squeeze out a considerable quantity of the vitreous."

Wright of Colombus, Ohio, published a paper in 1884 and another recently in Fisher's book on *Cataract* on this subject.

Many of his countrymen claim for him precedence. Let such compare his papers with the above quotation and they will see that Wright's procedure is exactly the same as Macnamara's except that Wright is not so courageous in that he does not insert the curette in case the lens is not coming easily.

No doubt a coincidence, though Macnamara's book was read the world over by ophthalmologists. It was the foremost book of its time. It was larger than any treatise on medicine in the sixties and more condensed.

Next in time comes Col. Mulroney, I.M.S. His method was essentially the same as Macnamara's (*vide* Rai Bahadur Mehr Chand's paper in the *Proceedings of the Indian Medical Congress* of 1894). But to Mulroney belongs the credit of extending the method to all senile cataracts.

As far as I can see the method would have ended with Mulroney, as he never wrote a paper on the subject, had someone else not come on the scene. I happened to be that someone. I developed a technique radically different from anything which preceded me except in the fact that the essential expression was maintained. My predecessors, if a difficulty arose, were at the mercy of the patient. Difficulties *do* arise and under the circumstances the patient does not show us much mercy. I wrote up the case repeatedly;

* A paper read at the *Oxford Ophthalmological Congress*, 1926.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

I induced controversy and held the field against all comers. I incurred no end of hatred for doing so from the opposing school. It is a pleasure to be worth hating. The profession began to think; the outcome of this is the many methods of extraction by forceps, pneumatic and other, which appear in the field to-day.

Forceps, pneumatic and other.

I think the earliest extensive operator by the forceps method was the late Dr. Stancelaneau of Bucharest.

His method was to get hold of the capsule with a special forceps and simply to haul it out. Often a piece of capsule came instead of the lens. In this case it was finished as a capsulotomy operation, but not always. I was informed by a reliable member of the profession who paid him a visit pre-war that he left many of such lenses in the eye. A great objection to the method is the liability to pull a piece out of the capsule and the certainty of doing so in the case of every Morgagnian cataract. Such are all the Kalt forceps proceedings except Knapp's, i.e., simply to haul out the lens by the grip on its capsule. Knapp on a visit to me was greatly struck by the ease and safety with which the Morgagnian or soft cataract could be expressed if made to turn a summersault and come out lower edge foremost, (*vide* Fig. 1),

FIG. 1.—THE DELIVERY OF THE SOFT (MORGAGNIAN) CATARACT AS A "TUMBLER" LOWER EDGE FIRST.

The point of the lens hook is twisted backward and downward until it gets a grip on the sclero-corneal ring. It is then used to pull the eye toward the patient's feet (arrow A), sufficient backward pressure to prevent it slipping being kept up (arrow B). The lens dislocates below at once and rolls up under the point on the lens hook, remaining attached to the suspensory ligament above.

and put the principle into practice with his capsule forceps. He gets hold of the capsule near its lower border and either dislocates the lens there first or brings a piece of the capsule with him. If the former he withdraws his forceps and expresses the lens as a "tumbler" by pressure with a squint hook over the sclero-cornea. He thus obtains the same security from escape of vitreous with the hard as well as with the soft lens.

I suggested to him when he got the forceps grip to use the squint hook on the exterior at the same time to assist in dislocation and thus be less liable to tear the capsule. I have recently heard from him that he tried the squint hook thus and that he is very pleased with the result.

In my tour in the U. S. A. and in Canada in 1921 everywhere I advised those using Barraquer's apparatus and the Kalt forceps method to use the squint hook thus to assist in dislocating the lens. The Greens use Barraquer's instrument in this way. How much extraction and how much expression is in the result it would be difficult to say. The Greens were highly skilled with the squint hook before they commenced Barraquer's proceeding.

Early in my experience I tried to make the hard lens tumble solely by pressure from without (placing the squint hook over the sclerotic for the purpose) after I had succeeded in making the Morgagnian cataract do so, knowing that if successful the risk of escape of vitreous in the hands of the average operator would be negligible. Unfortunately I had two cases of expulsive choroidal hæmorrhage in about 50 cases on the first day, and stopped, attributing these cases to the method.

I published a paper at the time in the *Indian Medical Gazette* stating these facts, but I now find that I was mistaken in my judgment and have reverted to the method. It is successful beyond my expectations. It is so simple that anyone with a little experience of ophthalmic operating should find no difficulty with it. The operator is master of the situation with the most difficult hard senile cataract (*vide* Fig. 2).

FIG. 2.—THE DELIVERY OF THE HARD CATARACT AS A TUMBLER.

In Fig. (*a*) the upper edge of the lens is prevented from moving forward by spoon pressure over the wound while its lower edge is driven forward by the hydrostatic pressure of the vitreous, raised with the lens hook over the sclerotic. In Fig. (*b*) the suspensory ligament has been torn from the lens below and the point of the lens hook has been slipped up on to the cornea behind the advancing lower edge, while in Fig. (*c*) the spoon has been lifted off the wound and the cornea is being tucked in behind the lens.

These are big claims, but I am absolutely satisfied that time will justify every one of them.

A friend wrote to me—"The combined pressure method gives one such a sense of security. I did a pair of cataracts in a young man recently which took some shifting. I expect if they heard of it ..... would erase me from the registers."

I am absolutely confident that it is destined to supplant all other methods of dealing with the hard senile cataract, whether by capsulotomy, Kalt forceps, Barraquer's method, or the method which I formerly adopted. It does not require extensive training, and gets over the bugbear of escape of vitreous. It gives the operator confidence that he is not going to be landed in difficulties and to have to change horses in midstream—the most disheartening of all things to a comparatively unskilled surgeon: it requires no special or complicated instrument, liable to go out of order at the wrong moment.

Before concluding I wish to deal with the operation practised by Barraquer.

In his most recent article—Fisher's *Senile Cataract* (1923)—he says:—

"Considering the extremes in the methods that I wish to criticise, it is easily seen that the defects of those techniques consist in leaving the remains of the lesion in the interior of the eye or in producing ectopias and traumatism in the intra-ocular organs, and that the ideal method consists in cutting the zonula and drawing the entire cataract with gentleness to the exterior without either pressure, stretching, or violence."

Phacerosis consists in drawing the crystalline lens by its anterior surface, separating it mechanically without either traction or violence of the zonula, and extracting it completely out of the eyeball without having produced ectopias or traumatism to the intra-ocular structures. The instrument employed called the Erisifaco is nothing more than a pneumatic forceps and a zonulatome.

Later on in the same article—Fisher's *Senile Cataract* (1923)—he says, "Do not think the Erisifaco is an instrument which automatically removes the cataract."

In his article in *La Clinique Ophthalmologique*, written in April 1919, he gives statistics of his first thousand cases:—

Hernia of the vitreous	7	cases.
Inversions of the flap	2	,,
Ruptures of capsules	4	,,
Dislocations of the lens	3	,,
Infections	2	,,
Prolapse of iris	7	,,
Hæmorrhage of the anterior chamber	5	,,
Incarcerations of the zonule	5	,,
Expulsive hæmorrhage	1	,,

Of these 1,000 cases:—

219 were simple extractions
530 with a Hess' iridectomy
251 with an ordinary iridectomy.

Taken on its face value this is all very seductive. A violent act without violence! And what results! How many have been seduced and have tried the method? Not a single man has succeeded except Barraquer himself. No one may question the fact that Barraquer can do it and do it well and that he gets good results. What is the explanation? The explanation is in my opinion that his would-be followers implicitly followed his instructions in every detail. In doing so they discovered that the *Erisifaco* is truly not an instrument "which automatically removes the cataract."

I will not admit that many of those who failed do not possess as good hands and are not as able men as Barraquer.

He directs them to make an incision of 144 degrees. 190 to 200 is the proper incision for Barraquer's operation. 144 degrees is impossible. We have to remember that *the lens and an instrument* have to come out of this wound. He gives diagrams of the lens after removal by expression or by Kalt forceps methods which are absolutely untrue to fact, showing that we tear out the zonula with the lens. I defy any man to demonstrate this fact. He says that this "magic box" acts in some way as a zonulatome and if not properly regulated brings out similar tags of zonule. This again I say is not fact. I defy him to demonstrate it. His observations are done on post-mortem human cataractous eyes. Where does he get them?

The instructions he lays down about regulating the instrument are inconsistent with themselves as any student of physics will at once observe.

I refuse to admit that there is any magic in his "vibrations." It is simply a vacuum forceps. Where in my opinion his would-be followers have failed chiefly is in "gently drawing out the lens" as the name of the instrument would indicate.

A friend of mine recently saw him do a cataract in a child successfully. The instrument has not 1|20th part of the power necessary to do this, for the lens in a child is at least ten times more firmly anchored than a senile cataract. In fact the instrument has only power enough to draw out an occasional senile cataract which happens to be very lightly anchored. What is the explanation? He is in my opinion dislocating the lens by pushing it straight backward and when dislocated completely rolling it over on its back and pushing it forward through the pupil with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the instrument right behind it. The instrument has ample power for this purpose because it has only to keep contact with the lens, no traction being exerted upon it. I thus challenge the whole of his instructions and say that his would-be followers would be well advised to throw them overboard completely and to exercise their own untrammelled judgment, and I have no doubt they will succeed as well as Barraquer.

The figures of his results of his first thousand cases are infinitely finer than any of us could ever hope to attain.

Finally, the following table of statistics will be of interest to those who hold that intracapsular extraction is on its trial, and that if it does succeed the expression method will

FIG. 3.— THE UPRIGHT DELIVERY OF AN EASILY DISLOCATED HARD CATARACT.

Figure (*a*) represents the lens hook laid on the flat over the lower part of the cornea, the point above. The arrow shows the direction in which the point is moved by rolling the handle of the instrument between the thumb and fingers. The lens dislocates at once and subsequent figures show the direction of pressure changed to follow it up as it emerges. The vitreous suffers no deformity.

The section views are copied from drawings sent by Colonel Smith and the front views are original sketches by Dr. D. T. Vail, Sr., of Cincinnati.

have to make way for some of the forceps methods. In these figures the Punjab accounts for close on 19,000 intracapsular extractions in the year, while the figures of the trans-Indus mission hospitals which are not included in the Punjab statistics amount to well over 2,000 per annum. The other provinces generally go in for capsulotomy. In North Western India if a surgeon cuts for stone in the bladder his practice will be severely limited—the patients demand crushing and will go elsewhere. The situation there is similar to that with cataract—the intracapsular operation (expression from without) is demanded and the hospitals where capsulotomy is practised are empty.

The above figures (extracted from the official records of the India Office) do not include the Punjab Frontier since 1913, nor do they include mission hospital work, e.g., the Bombay figures do not include the work done by Dr. Holland at Shikarpur though in the Bombay Province, nor do they include the Central Province and the Foreign Department, which is more than one-third of India.

When I commenced work in the Punjab in 1895 the lens coucher was doing most of the work; the capsulotomy operation could hardly hold its own against him. Every day we saw the result of his work. Now he has been put under by the intracapsular operation and you seldom see a case of his work; not so in the other provinces where the capsulotomy operation is practised.

The argument is often advanced that cataract is very much more prevalent in the Punjab than in the rest of India, but this is not the case—it is equally prevalent all over India, and when the surgeons in other parts of India become as accomplished at the intracapsular operation as they are in the Punjab their figures will mount up in proportion to their populations as they have done in North Western India.

In the face of these figures it is amusing to hear Britons, Americans and Germans talk as if their voice would decide what is the best operation, considering the smallness of their experience. The verdict of the Indian peasant is destined to decide the treatment of cataract as it has decided that of stone in the bladder. It is often said that the Punjabi is easily satisfied, but this is not the case. The Punjab peasantry are about as highly utilitarian and as exacting as any peasantry in the world. When the patient returns from hospital the results of his operation are discussed and criticised round the village hookah with the itinerant priest, who passes the word from village hookah to village hookah. It is there

FIG. 4.—THE UPRIGHT DELIVERY OF THE MORE FIRMLY ANCHORED HARD CATARACT.

The lens refuses to dislocate on the first backward twist of the point of the lens hook.

So pressure has to be made with the heel as well as the point of the lens hook to drive the lens forward by the hydrostatic pressure of the vitreous. The suspensory ligament is shown on the point of parting from the lens in Fig. (*b*) while in Fig. (*c*) the result which follows in heavy hands is shown. The pressure with the heel of the hook toward the optic nerve has not been relaxed the moment the ligament has given way, and vitreous is pressed out along with the lens and above it; while in Fig. (*d*) the heel has been lifted out the right moment; the pressure relaxed and altered in direction.

that the reputation of hospitals is made or marred and the fate of rival operations is decided. The result of the verdict is shewn in the fourfold increase of the statistics for the Punjab during the last thirty years, solely on the basis of intracapsular extraction, while in the other provinces where capsulotomy is

practised the figures have remained almost stationary.

These "big battalions" constitute an argument which cannot be ignored.

MASS TREATMENT FOR HOOKWORM INFECTION ON TEA ESTATES IN ASSAM.

By DR. E. MILFORD RICE, M.D.,

Langla, Sylhet.

(Read before the Surma Valley Division, British Medical Association in November 1926.)

THE tea estates under consideration are located in the Sylhet District which is situated in the south-western portion of the Province of Assam, bordering on Eastern Bengal. These tea estates are in an area about twenty-five miles long and about fifteen miles wide, all being on fairly high ground which is intersected by rice paddy fields. The rainfall in the district averages about one hundred and ten inches *per annum* and is distributed fairly evenly through the months of May to October inclusive, except for an occasional heavy rain just before this period and a few very light showers during the cold weather months. The mass treatments were therefore given between the 1st February and the 6th April, this being the driest time of the year and there being smaller chances of the coolies becoming re-infected then.

The coolies on these tea estates have been recruited from Madras, the Central Provinces, United Provinces and a few from Bihar and Orissa. About 80 per cent. of the labourers employed are old coolies who have been employed on the estates for years, the remainder being coolies who have been recruited year by year and who usually arrive from their various countries infected with hookworm. This being the case, new coolies are a constant source of infection and they should all be treated immediately upon their arrival upon an estate. No labour is locally recruited but villagers do, on occasions, come into the various estates to work by the day, but they do not live in the lines and are therefore not to be considered from the standpoint of infecting labour in estate lines. Coolie houses are usually built in streets where the available land will allow, but in many instances they are very badly scattered due to the hilly formation of the land in the Sylhet District. In some instances the lines are surrounded by jungle, but usually there is tea or rice paddy land on one or more sides. Few tea estates have any definite latrines except those which are required by the Factory Act, and coolies generally pick out defæcation areas in the neighbourhood of their houses, the majority seeking nearby jungle, tea or other screening, while others are not so particular and defæcate in the open in the immediate area around their houses or in open rice paddy land. The general habit is to stick to the one localized area and these defæcation areas become constant sources of direct re-infection as well as feeding places for pigs, dogs and cattle, who, in turn, deposit their hookworm-laden fæces in the lines where infection of the coolies may again take place. Ramsey (*Indian Med. Gaz.*, Sept., 1923) says: "The reason the pig is so dangerous in spreading hookworm is that having gorged himself with human fæces from the jungle around the lines, he returns with his fæcal-laden bowel to disseminate his helminthic and protozoal infections around the coolie huts." This certainly applies to dogs as well and may even apply to cattle. Coolie houses are usually built of bamboo with thatch roofs, the bamboo walls being plastered with clay mixed with fresh cattle manure. The women do this work and this may account for the relatively

higher e.p.g. (eggs per gramme) counts in the female if it can be definitely proved that the eggs of the hookworm pass through cattle without harm.

The mass treatment of coolies was started in February 1925, when 8,516 coolies were treated between that time and April 6th of that year. A further 1,223 were treated in February 1926, making a total of 9,739. (*See* Table I.)

No coolie who had jaundice or any enlargement of the liver was treated, but no other precautions were taken, other than to have the chowkidars (line watchmen) instruct all coolies that they were not to drink spirits for 24 hours before or after they had received treatment. They were also told that they were to have their usual morning meal before coming to the general muster for treatment. This series of 9,739 coolies were treated with carbon tetrachloride in magnesium sulphate solution. Each adult coolie between the ages of 18 and 50 was given 60 minims of carbon tetrachloride, while children under 18 years were given three minims for every year of their age, adults over 50 being given doses ranging from 25 to 50 minims. Adults of 18 to 50 years of age were given one ounce of saturated solution magnesium sulphate, the others being given amounts in proportion to the dose of carbon tetrachloride they were to receive.

As many as seven hundred coolies were treated in one day by having them line up according to the pay lists and passing by the treatment table as their names were called. As their names were called they passed by the first examiner (usually the tea estate doctor babu), who examined them for jaundice, any enlargement of the liver, and to see that they were not under the influence of spirits. If any of these were found the coolie was passed out of the line and not treated, a record of his or her name being kept for future treatment. Any coolie who objected was not treated against his will but after the first few days there was no trouble in treating them all and those who had refused treatment the first day usually came up later on for their treatment. All pregnant women were given the same treatment as the other women. After having passed the first examiner they proceeded to the table where the doses were mixed by the second examiner (usually the writer). Here the magnesium sulphate solution was measured into small medicine glasses, the carbon tetrachloride being measured in a glass syringe calibrated in minims. By forcing the plunger of the syringe down quickly the carbon tetrachloride is shot with some considerable force into the magnesium sulphate solution which holds it in suspension sufficiently long for the coolie to drink it with the minimum amount of danger of the fumes being inhaled. Immediately the dose is taken, the coolie is asked to open his mouth so that the examiner can see that he has not retained the dose without swallowing it. This latter procedure is important, as should the coolie hold the mixture in his mouth and breathe over it there is a danger of the vapour coming in contact with the mucous membranes of the respiratory tract which might produce a reflex stoppage of the respiratory functions as has been reported. For the same reason, carbon tetrachloride should never be given to a child who is struggling.

In this series of 9,739 cases treated with carbon tetrachloride and magnesium sulphate solution there were no fatalities as the result of, or immediately following, the treatment. About 3 per cent. of the cases complained of slight abdominal pain, vertigo, nausea and in a few cases vomiting some hours after the treatment, but the symptoms were all transitory. About 1 per cent. said they had passed round-worms but no definite records of this were kept.

Of the coolies treated in 1925, 337 were coolies of the Terapassa Tea Estate and 296 of these same coolies were again treated with carbon tetrachloride in 1926, while a further 46 were treated with carbon tetrachloride in conjunction with oil of chenopodium. As the entire population of this tea estate is only 422, nearly every coolie, except for very young children and old dependents, was treated for the second time in twelve months.

At the general muster on the Lungla Tea Estate in 1925, 1,052 coolies were treated with carbon tetrachloride and a further 451 were treated with carbon tetrachloride and oil of chenopodium during the rest of the year, these latter being coolies who were not present at the muster and some few very anæmic coolies. This makes a total of 1,503 cases treated in a population of 1,675. Some few of these cases may have been treated twice, but the number is negligible. The 451 cases treated with carbon tetrachloride and oil of chenopodium are not included in Table I, but it may be of interest to know that about 50 per cent. of these latter cases passed round-worms as well as hookworms.

In May 1926, Dr. Asa C. Chandler, of the Calcutta School of Tropical Medicine, who was making a hookworm survey of India, visited this district, and while here took the opportunity of determining the effect of the mass treatments which had been carried out on the Lungla and Terapassa Tea Estates. Dr. Chandler (*Ind. Jour. Med. Res.*, Oct. 1926), published tables showing his findings and has very kindly given me permission to use portions of these tables which I am modifying to show what treatments have been given, populations, etc., but in no way have I altered

his figures. (*See Table* II.) Those figures in heavy type are Chandler's, those in light type are my own.

It will be seen from a perusal of Table II, that the coolies of the Terapasaa Tea Estate have had two mass treatments, the first in 1925 and the second in 1926; those of the Lungla Tea Estate, one mass treatment in 1925 only. In this Table are shown figures for the two *bastis* (villages) which are adjacent to the two tea estates, the *ryots* of which have received no treatment, and which shows the approximate relationship between treated and untreated groups. In studying the figures for the total per cent. infected, average e.p.g., and the estimated average worms per person, those for the Manu and Basudeopur *bastis* are so nearly alike that it is unnecessary to consider them separately. In all probability, taking into consideration the topography, type of lines, and the proximity of the *bastis* to the tea estates, had this survey been carried out prior to the time mass treatments were given, the tea estate figures would have been much the same as those for the *bastis*.

After averaging the figures for the *bastis*, the Lungla Tea Estate coolies, after one mass treatment, show a reduction of 13.3 per cent. in the total per cent. infected, while the Terapassa Tea Estate coolies show a reduction of 32.5 per cent. after two mass treatments. The average e.p.g. counts show even more striking results, the Lungla coolies only averaging 1|5th as many e.p.g. as the *basti ryots* (171 : 867) while the Terapassa coolies only have 1|14th as many (62 : 867). This shows a considerable reduction in coolies infected and also shows that those coolies who are infected still have very much lighter infections than have the *basti ryots*; no coolie of the Lungla group having more than 2,000 e.p.g. and none of the Terapassa group more than 500 e.p.g. (This is excluding the one case at Terapassa who had 6,300 e.p.g. which Dr. Chandler has not entered in his figures as the woman had deliberately put her fingers down her throat and vomited on the two occasions on which she had been treated.) Since this case has been brought to light all coolies have been cautioned against this practice as there is a real danger of the carbon tetrachloride being inhaled when vomited immediately after it has been taken.

CONCLUSIONS.

(1) Mass treatments for hookworm disease should be given in February and March on tea estates in Assam.

(2) Most newly recruited coolies have hookworm infection when they arrive on tea estates from their respective countries and should be treated upon arrival.

(3) If cattle manure contains active hookworm eggs, heavy infections might be expected through coolies using it as plaster for walls and floors of their houses.

(4) Pigs and dogs certainly, and possibly cattle, by passing their stools in coolie lines after eating human fæces, are a means of reinfection.

(5) Carbon tetrachloride, given in 60-minim doses to adults (18 to 50 years of age) in one ounce of saturated magnesium sulphate solution and after a morning meal, is a safe drug to use in tea estate practice. It is also safe to use for children and the aged if given in proportionate doses.

(6) No precautions are necessary other than to warn patients that they are not to take alcohol or spirits for 24 hours before or after treatment and to treat no case with any liver complaint.

(7) Pregnant women can be given the same dose as other coolies.

(8) The number of infections can be materially reduced by such mass treatments.

(9) Heavy infections can be reduced to harmless ones by such mass treatments.

AN ANALYSIS OF 108 INTRAVENOUS IODINE INJECTIONS.

By CH. KRISHNAMURTY, L.M.P.,

Sub-Assistant Surgeon, Sompeta, Ganjam District.

DURING the year 1925-26, partly from the dearth of drugs and partly with a view to test its results, 108 intravenous iodine injections were given for the following conditions in this dispensary.

1. *Respiratory diseases* (except tubercle of the lung)—13.

(*a*) For sero-fibrinous pleurisy, recurrent—9.

(*b*) For intractable bronchitis, generally resistant to expectorants—4.

The results were satisfactory. The injections for pleurisy represent two cases. In one case which used to recur almost every month 8 intravenous injections were given, first a series of six, one every day and later one every alternate day. The patient has not had his usual recurrence for some months now. In the second case the patient was getting salycylates, iodides, etc., with no marked improvement. After a single injection the pleural friction disappeared and the mixture appeared to work better. The four injections for bronchitis represent two cases which were running a very prolonged course, now clearing up in one area and attacking another. In both the cases two injections, one each on

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

alternate days, brought down the temperature and cleared the lungs wonderfully. Mixture by mouth was also being continued at the same time.

(2) *Diseases of organs of locomotion*—19.

These were cases of rheumatoid arthritis, chronic synovitis and gonorrhœal rheumatism. These represent six cases. A cure was found with six injections in one case and the rest were greatly relieved, but these latter did not have an appreciable number of injections, each of them having 2 to 3 and discontinuing for several reasons, mostly being satisfied with the relief and unable to spare time.

(3) *Lymphangitis*—10.

Two cases of lymphangitis were treated and they were both cured. These were both chronic and of some years' duration. One had six and the other 4 injections.

(4) *Cellulitis, chronic ulcers, phagedena, and necrosis of bone*—12.

The inflammation in cases of cellulitis used to improve after one or two injections. When there was obvious suppuration, multiple incisions and continuous antiseptic baths were also used. In cases of chronic ulcers lasting for months with indurated edges and where scraping was refused, 2 or 3 iodine injections stimulated them to heal fast. In cases of phagedena the improvement was remarkable, even with the first injection. In cases of necrosis of bones the sequestrum used to separate with great rapidity and the discharge from the sinus became less foul every day; the wound used to close ultimately.

(5) *Furunculosis*—7.

During the height of summer some people are in the habit of suffering from crop after crop of boils on the face, hands and anywhere on the body. All external measures such as zinc, boric, ichthyol, antiphlogistine, etc., give only temporary relief. I have seen a course of Kalazana tablets with one or two iodine injections improve the condition marvellously.

(6) *Scabies*—22.

Persons suffering from scabies in these parts are a common sight at this dispensary. Cases were selected for iodine treatment. Such as had it all over the body or those suffering for several months were chosen. About three to four injections with nothing but general cleanliness locally twice a day improved them all.

(7) *Enlarged lymphatic glands, scrofular and otherwise*—7.

It is unfortunate that none of the cases underwent a thorough course. They were all improved after two or three injections each.

(8) The other 18 injections were—2 for chronic otorrhœa,—cured: 2 for pyæmia—the case stopped developing further abscesses and the abscesses then existing began to heal; 2 for general deblity, where the patient felt much better; 12 for cases of tuberculosis of the lung, where sodium morrhate had stopped showing further improvement, or alternately with sodium morrhate. Two cases were thus tried and showed marked improvement.

In all the above cases the prescription given in the *Indian Medical Gazette* (iodine 1 dr., potassium iodide 1 dr., aqua distillata 5 oz. 2 dr.) was followed. If 1 dr. is taken to be equivalent to 27½ grains according to Avoirduposis weight, 20 minims of such a solution contains about one-fifth of grain of iodine, and with the dose suggested (3 to 6 minims) the iodine content is far too little. I therefore employed the above prescription with 10 minims as my initial dose, and increased it by 5 minims at every other injection until I reached 40 minims, which is approximately equal to half a grain of iodine. Intravenous iodine treatment in comparison with other methods is very cheap, saves a lot of trouble, and from the leucocytosis it produces may be claimed as a panacea. A time may come when many of the drugs in the *Pharmacopœia* may disappear and be displaced by iodine.

NOTES ON INFANTILE CIRRHOSIS OF THE LIVER.

By M. A. KRISHNA IYER, L.M.P.,

Central Jail Hospital, Coimbatore.

THE real and specific cause of this disease is not yet known. Whether it is due to the custom of artificial feeding in wealthy people with all kinds of patent foods irrespective of the indications and medical advice for the infant, or due to the remote or congenital effects of venereal diseases such as syphilis, etc., in the parents, or to feeding the infants concerned with pure cow's milk in unsuitable and large quantities, or to too early feeding of infants with starchy and fatty foods, or whether it is a food deficiency disease, has yet to be proved. Whatever may be the cause or causes of the disease, it is a fact that this disease is prevalent in those parts of South India where the use of patent and tinned foods is the rule in every well-to-do household, also in families where there is no regular system of giving foods suitable to a particular baby at a certain age. It is well known to all the Hindus that one of the religious observances during the period of one's life from birth to death is the food-giving ceremony, i.e., the *annaprasanam*. This ceremony is performed when the child attains a year of its existence

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

or thereabouts. This is a ceremony in which the child gets its "rice food" for the first time. It may be that this system has been made in accordance with the hygienic principles, like many other so-called mystic systems for which by the light of modern knowledge we can give a scientific explanation. People in the old days might have found out that giving rice or such other starchy food to infants when they are younger than a fixed age would be detrimental to their health. Nowadays as there is a wholesale condemnation of the so-called mystic ideas without duly considering their possible scientific basis, it is no wonder that many a disease, quite unknown during ancient days, has sprung up among us now. That infantile cirrhosis of the liver, though the exact ætiology of it is unknown, whether due to child's food either in excess or deficiency, contributes one of the important causes of infantile mortality in India is an almost settled fact. As mentioned above, the ceremony of giving rice for the first time practised in the Hindu families of Malabar, though this function ought to be conducted in every orthodox Hindu family, is not generally nowadays performed in the Tamil districts of South India. Infantile cirrhosis was almost unknown in Malabar, including the two Native States. So much so that the grandmothers of these parts do not even now know that there is such a disease at all. But on the other hand, the first thought that strikes a young pregnant woman in the Tamil district to-day is how to save her future infant from the disease. Evidently it goes without saying that infantile cirrhosis of the liver is very common among the infant population of these Eastern Districts. Is it possible that the early administration of starch and of fatty foods acts as a primary cause of its incidence? Whatever it is, one can say with confidence that rearing of infants in Tamil districts with a certain definite routine with regard to food, etc., is not what it ought to be. Not only is there great irregularity in their food as regards quantity and quality, but also the parents pay very little attention to personal hygiene. For example daily baths are not given regulary in these Eastern Districts which are very hot in summer.

Religious ceremonies and observances are numerous in the Hindu household, when all kinds of sweet dishes are prepared. The infant gets easy access to the eatables; one determined cry secures for him a couple of sweetmeat cakes. Sweet and starchy preparations will invariably be served up during a ceremony and not a month passes without a ceremony or two, not to mention the daily preparation of similar foodstuffs for others in the family.

The next point for consideration is the administration of patent foods, irrespective of their quality and of the advice of medical men. It is customary nowadays among the Brahmin population of the district in which community the disease is most common, among the rich as well as the poor, to have ready bottles or tins of patent foods as soon as a woman's accouchment period approaches. Whether the use of such foods is the cause of the disease or not, it can be definitely proved that many alimentary disorders which always precede infantile cirrhosis are caused by the injudicious administration of such foods. Even from the second or the third day of an infant's life cow's milk with sugar is administered on the plea that the mother has not sufficient milk to feed her baby. We all know that cow's milk administered plain as it is will not be digested even by an older child. How much less is the power of the digestive mechanism of a poor baby a few days old? How could one legitimately think that such injudicious administration is not unintentional homicide? Is it not over-taxing the liver of the new born baby and paving the way for infantile cirrhosis?

A further point is the prevalence of syphilis among the parents. Though syphilitic cirrhosis of the liver stands by itself as a separate disease, there is not sufficient evidence to say whether paternal syphilis acts as a cause of the occurrence of infantile cirrhosis. Though not all, many of the cases of infantile cirrhosis of the liver which come to one's notice have a syphilitic taint in the parents. Also there are some cases of infantile cirrhosis which may be really syphilitic cirrhosis.

Alcoholism among the parents, though not uncommon, cannot be included among the ætiological factors. If alcoholism in the parents is one of the causes of infantile cirrhosis then the children of the poorer and lower classes ought to be affected in large numbers, instead of its high prevalent incidence among Brahmins and other high caste Hindus and Muhammadans where the drink evil is at a minimum.

Suspicious causes such as malaria, kala-azar, rickets, scurvy, etc., can very well be excluded as ætiological agents, as such ailments have a definite and clear cut clinical history with them.

The disease is found mostly among Brahmins and other high class Hindus and Muhammadans. But it is rare among the Brahmin population of Malabar: and still less in other castes. The daily bath given to the baby with withholding of carbohydrates, etc., until the infant is able to digest them, the rainy climates of Malabar, the lower incidence of venereal diseases among the parents, the invariable breast feeding of infants in whatever sphere of life, may afford protection to the infants of Malabar from this dreadful disease.

OBSERVATIONS ON THE PHARMACOLOGICAL ACTION OF CONESSINE, THE ALKALOID OF *HOLARRHENA ANTI-DYSENTERICA*.

By R. N. CHOPRA, M.A., M.D., B.Ch. (Cantab.), MAJOR, I.M.S.,
Professor of Pharmacology, in collaboration with—

J. C. GUPTA, M.B. (Cal.),

J. C. DAVID, M.B., B.S.,

and

S. GHOSH, D.SC., F.R.S. (Edin.),

Professor of Chemistry, Calcutta School of Tropical Medicine and Hygiene.

Holarrhena antidysenterica is a small deciduous tree with white flowers, belonging to the natural order *Apocynaceæ*, from which are derived most plants of the digitalis group. This is a point of interest because the active principles of *H. antidysenterica* also have a selective action on the muscle of the heart. This plant has many Sanskrit names, the best known being *kutaja* and *kalinga*. The other vernacular names are:—*kurchee* (Bengali), *kureya, dudhi* (Hindi) and *kulappalai* (Tamil). The seeds are called *indrayava* or "Indra's seeds" in Sanskrit and *indrajab* in Hindi. In Persian it is known as *indrajavatalkh* and it is well known in Arabian medicine.

The plant is fabled to have sprung from the drops of "Amrita" or water of life which fell on the ground from the bodies of Rama's monkeys, which were restored to life by the god Indra. It is a native of the tropical Himalayas, going up to an altitude of 3,500 feet; it is also found throughout the dry forests of India, even as far south as Travancore. This plant is often confused with another one of the same family called *Wrightia tinctoria*, which is medically inert. Linnæus was originally responsible for this confusion, but it was rectified by Brown (1809), who revised the whole of the *Apocynaceæ* family. Although differentiation between *Holarrhena antidysenterica* and *Wrightia tinctoria* has thus been made for a hundred years, yet they are often mistaken for one another and this fact probably accounts for the drug having fallen into disrepute. *Wrightia*, however, has white jasmine-like flowers with a fragrant odour, while the flowers of *Holarrhena* are odourless. Furthe., the *Wrightia* bark can be easily identified because of its reddish brown colour and its smooth appearance as compared with the *Holarrhena* bark, which is thicker and is of a dirty white or buff colour and has a markedly bitter taste. The seeds of *Holarrhena* resemble oats; they are very bitter and are contained in long follicles about the thickness of a quill. They have a tuft of hairs on the end most remote from the foot-stalk, whilst in the *Wrightia* seeds the tuft is on the end next to the foot-stalk.

A kind of indigo dye is extracted from the leaves, and they are used as fodder in certain parts of the Punjab. The wood is white, soft, and even-grained and is used for carvings and for making furniture. The bark of both the stem and the root and the seeds are amongst the most important of the medicines of the Hindu Materia Medica. The bark is considered to be a powerful antidysenteric, while the seeds are said to have astringent, febrifuge, antidysenteric and anthelmintic properties. In Arabian medicine the seeds are considered carminative and astringent, valuable in pulmonary affections, tonic, lithontriptic and aphrodisiac. Combined with honey and saffron they are made into pessaries which are supposed to favour conception. The pharmacopœia of India classed *H. antidysenterica* amongst the non-official remedies but reported very favourably on its therapeutic qualities. The Hindu physicians use it in form of a fluid extract or expressed juice of the fresh plant, a compound decoction and a confection prepared from the bark and the seeds are often given in dysentery with beneficial results. Kanny Lall Dey was so struck with its therapeutic efficacy that he advocated that it should be made official in the *British Pharmacopœia*.

H. antidysenterica has been introduced into Western medicine and has lately been tried somewhat extensively in the treatment of amœbic dysentery. The remedy was at first used in the form of an infusion of the root bark; this however, is very bitter and most unpalatable. Burroughs, Wellcome & Co., have put "Tabloids" made from the bark on the market and in this form it is easily taken and has been combined with emetine treatment with beneficial results. Major R. Knowles, I. M. S., reports to us that he has found the simultaneous administration of emetine hypodermically and "Tabloid" extract *kurchi corticis* orally of marked value in the treatment of amœbic dysentery.

Chemistry of the Bark.

The active principles of the bark of *H. antidysenterica* are the alkaloids conessine and holarrhenine. An artificial oxidation product, oxy-conessine, has also been prepared. Conessine was first isolated by Haines (1858), and Stenhouse (1864) independently prepared it from the seeds. In 1880, R. C. Datta in collaboration with R. D. Ghosh isolated the alkaloid under the name of "kurchicine" and this was administered in chronic dysentery in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

doses of 2 to 5 grs. Pyman (1919) described the chemical properties of the two alkaloids.

H. antidysenterica and the allied species *H. africana,* and *H. congolensis* were the subjects of various papers at different times. We do not think it necessary therefore to go into the details of the process of extraction of the alkaloids contained in it. We here summarise briefly the process we have followed for the isolation of conessine for our work.

An assay of the powdered bark shows that it contains 1.5 per cent. of total alkaloids by weight, but it is difficult to get conessine in pure condition out of the crude total alkaloids, much being lost in the process of purification. The following methods were employed for the isolation of the alkaloid:

(*a*). The powdered bark was exhausted with 2.0 per cent. HCl by cold percolation. The acid solution was then nearly neutralized (faintly alkaline) with NaOH, and the precipitate which formed was filtered off. The filtrate was then treated with excess of strong NH_4OH and the liberated base taken up with chloroform. On distilling off the chloroform, a brown oily mass of crude alkaloid was obtained. This was dissolved in the smallest quantity of absolute alcohol, and a saturated solution of oxalic acid in alcohol was added till the solution was distinctly acid. The oxalate which formed was then filtered, washed with absolute alcohol, dissolved in water, treated with excess of strong NH_4OH and the base taken up with ether. The ethereal solution on concentration deposits a nearly white amorphous powder which has a melting point of 105 to 108°C. By repeating the above process, viz., re-forming the oxalate and again re-liberating the base the alkaloid having a melting point of 121.5°C. was obtained.

(*b*). The above method being very laborious and tedious, the following method was tried and found to give good results. The finely powdered bark was mixed with 20 per cent. of its weight of lime (made up into a thin paste with water), dried in the air and exhausted with 90 per cent. alcohol. The main portion of the alcohol was distilled off and the remainder removed *in vacuo*. The residue was then extracted with dilute HCl several times till free from the alkaloid. The acid solution was then nearly neutralized with NaOH till a faint turbidity appeared. This removed a good deal of the colouring matter and other impurities though not without a slight loss of alkaloid. The solution with the precipitate was shaken up with ether, the ether separated, the aqueous solution filtered and the base precipitated with excess of strong ammonia. The liberated alkaloid was then taken up with ether, which on distillation gave a pale cream coloured semi-solid mass. This was dissolved in absolute alcohol and treated with a saturated alcoholic solution of tartaric acid. The tartrate formed was filtered, washed with absolute alcohol, dissolved in water, the alkaloid regenerated with strong ammonia and taken up with ether. After removal of the ether and keeping the residue exposed in the air for a few days we get the pure alkaloid with a melting point of 120-121°C.

Pharmacological Action of Conessine.

Keidal (1878) first attempted to work out the physiological action of conessine. His conclusions were that the alkaloid depressed the centres for conscious sensation in the brain and had also a depressing effect on the respiratory and vaso-motor centres in the medulla. It decreased the reflexes generally and it increased the peristaltic movement of the intestines. He concluded that conessine behaved in a general way like morphine and chloral hydrate.

Burn (1914) investigated the pharmacological action of conessine, oxy-conessine and holarrhenine. He found that conessine exerts a considerable narcotic action on frogs but has no appreciable effect in mammals. It has an anæsthetic effect on the cornea of the rabbit, though it does not produce any loss of sensation in the peripheral nerves when given subcutaneously. Conessine and holarrhenine according to him are both cardiac poisons, causing the isolated perfused heart to come to a standstill. They have a particularly destructive action on the tissues of the auriculo-ventricular bundle and when injected intravenously produce heart block. In small doses both the alkaloids when given intravenously produce a rise in the blood pressure, which is still seen after the vaso-constrictor nerve endings are paralysed with ergotoxine.

Brown (1922) tried the action of conessine on free living amœbæ and found that not only had the drug a marked amœbicidal action, but even in a dilution of 1 in 1,000,000 it was capable of inhibiting their growth in culture media. The action of conessine in this respect was equal to that of emetine. Neither of these alkaloids had any marked effect on the organisms of bacillary dysentery.

H. antidysenterica bark is now being largely used in treatment of dysentery and we carried out a series of experiments with a view to confirming the previous work and extending it in other directions. Our investigations were confined mainly to conessine, which is the chief alkaloid present in the bark of *H. antidysenterica* growing in India; holarrhenine only occurs in very small quantities. In most of our experiments we used conessine hydrochloride, but we also used the hydrobromide and the tartrate which were quite stable salts.

Action on Protozoa.

(*a*). Conessine salts have a marked action on the undifferentiated protoplasm, and free living and other protozoa are rapidly killed. Following the method of Henry and Brown (1923), we performed experiments to determine the comparative toxic effects of conessine hydrochloride and emetine hydrochloride on *Paramœcium caudatum* and other protozoa in the presence of alkali and without it.

For convenience in making comparable solutions, the alkaloidal solutions were made by dissolving a molecular weight (M) in grammes of the base in one litre of water and then diluting to the required strength. M|1,000 therefore means a molecular weight

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

in grams of the alkaloidal base in 1,000 litres and so on for other expressions M|100,000, etc.

The results are set out in the following tables:—

Results with P. caudatum.

		In presence of N|200 NaOH.	In absence of alkali.
	(a) *Conessine.*		
M|10	Conessine + culture (1 in 28)	Death instantaneous.	All dead after 1 or 2 secs.
M|100	Conessine + ,, (1 in 280)	All dead after 4 secs.	All dead after 10 secs.
M|1,000	Conessine + ,, (1 in 2,800)	All dead after 10 secs.	All dead after 19 secs.
M|10,000	Conessine + ,, (1 in 28,000)	All dead after 2 mins.	Alive even after 76 hrs.
M|100,000	Conessine + ,, (1 in 280,000)	Alive even after 20 hrs.	..
	(b) *Emetine.*		
M|10	Emetine + culture (1 in 20)	All dead almost instantaneously.	All dead in 3 secs.
M|100	Emetine + ,, (1 in 200)	Dead after 5 secs.	Dead after 15 secs.
M|1,000	Emetine + ,, (1 in 2,000)	Dead after 15 secs.	Dead after 15 mins.
M|10,000	Emetine + ,, (1 in 20,000)	Dead after 7 mins.	Alive even after 24 hrs.
M|100,000	Emetine + ,, (1 in 200,000)	Alive even after 64 hrs.	..

N.B.—*Controls.* Active cultures of *P. caudatum* were kept in presence of equal strength of the alkali and were found to be alive and active for 48 hours.

Equal volumes of the alkaloidal solutions, culture, and alkali were taken and therefore the actual concentration of alkali in the preparation was N|600.

pH of culture of *P. caudatum*	=	6.8
,, ,, Conessine hydrochloride ..	=	4.8
,, ,, N|200 NaOH	=	11.9
,, ,, N|600 ,, ...	=	11.5
,, ,, Emetine hydrochloride ..	=	6.8

(*b*). Free-living amœbæ were cultured in Clegg and Musgrave's medium. The culture from the plate was picked up by means of a platinum loop with a diameter of 3 mm. The experiments were generally carried out in the same way as those with *Paramœcium*, except that the observations were made on the warm stage of a microscope. The amœbæ were a mixture of *proteus* and *limax*.

Results with free-living amœbæ.

		In presence of N|200 NaOH.	In absence of alkali.
	(a) *Conessine.*		
M|10	Conessine + a loop of culture. (1 in 28)	Instantaneous death.	Death in 5 secs.
M|100	Conessine + ,, (1 in 280)	Dead after 2 to 4 secs.	Dead after 30 secs.
M|1,000	Conessine + ,, (1 in 2,800)	Dead after 1 min.	Dead after 3½ mins.
M|10,000	Conessine + ,, (1 in 28,000)	Dead after 3 mins.	Alive even after 1 hr.
M|100,000	Conessine + ,, (1 in 280,000)	Dead after 11 mins.	Alive even after 1 hr.
	(b) *Emetine.*		
M|100	Emetine + culture (1 in 200)	Dead after 10 secs.	Dead after 1 min.
M|1,000	Emetine + ,, (1 in 2,000)	Dead after 7 mins.	Dead after 30 mins.
M|10,000	Emetine + ,, (1 in 20,000)	Alive even after 30 mins.	Alive even after 1 hr.

N.B.—The final concentration of the alkali in the solution under test was about N|400. Controls were kept and were found to be alive and active after one hour.

pH of N|400 NaOH .. .. = 11.7

Experiments with Trichomonas hominis.

(*c*). A culture of *Trichomonas hominis* grown in Dobell and Laidlaw's medium for growing *E. histolytica* (i.e., inspissated serum covered with Ringer's and egg albumen) was used.

		In presence of N|200 NaCH.	In absence of alkali.
	(a) *Conessine.*		
M|100	Conessine + culture of *Trichomonas* (1 in 280)	Immediate death.	Dead with in 3 mins.
M|1,000	Conessine + ,, (1 in 2,800)	Dead after 25 secs.	Dead after 7 mins.
M|10,000	Conessine + ,, (1 in 28,000)	Dead after 48 mins.	Alive even after 1 hr.
M|100,000	Conessine + ,, (1 in 280,000)	Alive even after 1½ hrs.	Alive even after 1½ hrs.
	(b) *Emetine.*		
M|100	Emetine + culture of *Trichomonas.* (1 in 200)	Dead in 1 min.	Dead in 4 mins.
M|1,000	Emetine + ,, (1 in 2,000)	Dead after 13 mins.	Dead after 1½ hrs.
M|10,000	Emetine + ,, (1 in 20,000)	Alive even after 45 mins.	Alive even after 1½ hrs.

N.B.—Controls were kept in the presence of alkali and the flagellates were found to be alive after 3 hours. The final concentration of alkali in the solution under test was about N|600 (pH 11.5).

pH of Trichomonas culture .. = 6.45

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

We also tried the effect of these alkaloids on the free-living flagellate, *Bodo*, and found that both conessine and emetine had a more toxic action on this organism, the former killing in dilutions of 1 : 280,000 and emetine killing in 1 : 20,000 in alkaline medium.

Dale and Dobell (1917) observed that *E. histolytica* can sometimes withstand a 1 per cent. solution of emetine for half an hour. Dobell and Laidlaw (1926) tested the action of the ipecacuanha alkaloids on cultures of *E. histolytica* and found that emetine and cephæline alone of all the substances tested are able in very weak concentrations (1 in 50,000) to kill this amœba if allowed to act for sufficient time; further that *E. histolytica* alone of all the entozoic amœba studied is killed by such weak solutions of emetine. Emetine therefore has a specific action on *E. histolytica* cultures.

(*d*). We tested the comparative toxicity of conessine and emetine on these amœbæ, but in our experiments we used flakes of mucus from infected kittens containing *E. histolytica*. The solutions of the alkaloid were brought into contact with these on the warm stage of a microscope and the effects were carefully noted.

Results with E. histolytica.

		In presence of N|200 NaOH.	In absence of alkali.
(a) *Conessine.*			
M|100	Conessine+a loopful (1 in 280)) of the stools.	Instantaneous death.	Dead after 2 mins.

N.B.—The final concentration of the alkali in the solution under test was about N|400 (pH = 11.7). Controls were kept and the amœbæ in flakes of mucus were found to be alive and active after one hour when in contact with alkali and after three hours in the flakes alone.

From these series of experiments it will be seen that *P. caudatum* is killed in two minutes by 1 in 28,000 of conessine in an alkaline solution and 1 in 20,000 of emetine in 7 minutes under similar conditions. In the absence of alkali, the toxic effect was considerably weaker. In the case of the free-living amœbæ (*proteus* and *limax*), conessine proved lethal in 1 in 280,000 dilutions in alkaline solution as compared with 1 in 2,000 of emetine. In the case of intestinal flagellates, e.g., culture of *Trichomonas hominis*, neither of these alkaloids had any marked effect. In case of *E. histolytica* our experiments show that emetine kills these amœbæ present in flakes of mucus in dilutions of 1 in 200,000, and conessine is lethal in 1 in 280,000 in presence of alkali.

Effect of conessine on B. dysenteriæ (*Flexner*).

A Rideal Walker test was done and the results are tabulated below.

	2½ mins.	5 mins.	7½ mins.	10 mins.
Absolute Phenol ..	–	–	–	–
Conessine M|100 (1 in 280) ..	+	+	–	–
Conessine M|1,000 (1 in 28,000) ..	+	+	+	+
Conessine M|10,000 (1 in 28,000)	+	+	+	+
Conessine M|1,000,000 (1 in 280,000)	+	+	+	+

+ = growth – = no growth.

With conessine M|100 (1 in 280) all the bacilli (*B. Flexner*) were killed in 7½ minutes. As the alkaloid did not show any marked effect on the enteric group of bacteria no further experiments were performed.

Local Effects.

Subcutaneous or intramuscular injections of conessine salts set up marked œdema of the area round the site of injection. There are signs of congestion and hyperæmia at the site of injection, but no hæmorrhage or necrosis of tissues was observed even when 6 per cent. solutions were injected. The effects were visible a few hours after the injection, began to show signs of resolution after 24 hours, and disappeared almost completely after 48 hours.

Alimentary System.

Conessine has a bitter taste. When administered by the mouth it appears to have a depressing action on the digestive ferments. We tested the effect of the alkaloid *in vitro* on:—

Ptyalin.—Equal volumes of a 1 in 10 solution of saliva and a 1 per cent. solution of starch were taken in a series of 6 test tubes and conessine in mgms. was put into each tube so as to give different dilutions. These tubes were incubated in a water bath at 40°C. and readings were taken on a paraffined white plate every five minutes, mixing one drop of the solution from the test tubes with one drop of iodine solution and noting the end point when the blue colour of starch iodide ceased to appear. In the control tube with no conessine digestion was complete in 20 minutes, but starch was still present in the two test tubes containing 0.2 mgms. (1 in 10,000) of conessine and 0.4 mgms. (1 in 5,000) of conessine, showing that the action of ptyalin was inhibited.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Pepsin.—2 c.c. of a solution of 0.25 per cent. of pepsin in 0.2 per cent. HCl in water were put into a series of seven test tubes. One was kept as control, 1 c.c. of distilled water being added to it. Conessine was put into the other six test tubes so as to give different dilutions from 1 in 5,000 to 1 in 60,000, the amount in each test tube being made up to 3 c.c. Fifty mgms. of dried carmine stained fibrin were put into each tube and the whole lot transferred to a water bath kept at 40°C. After half an hour the tubes were taken out and the amount of digestion that had taken place in each tube was noted by the depth of pink carmine colour discharged by the fibrin in the process of digestion. Dilutions from 1 in 60,000 to 1 in 15,000 did not apparently interfere with the digestion but stronger concentrations up to 1 in 7,500 retarded it; in concentrations of 1 in 5,000 no digestion occurred.

Trypsin.—The effect of conessine on the digestion of proteins by trypsin was noted in

Graph I.

BLOOD PRESSURE, RESPIRATION, ETC.

(2)

(1)

(1) 5 mgms. conessine given into femoral vein causes the blood pressure to rise momentarily. This is followed by a marked fall which is persistent. The respiration is first stimulated but subsequently greatly depressed and slowed. (Drum stopped at X.)

(2) 0.5 mgms. conessine has produced a persistent fall of the blood pressure. The respiration is at first greatly stimulated and the depressed and slowed. Peristaltic movements of the intestines are augmented.

Digitized by Arya Samaj Foundation Chennai and eGangotri

the same way. Tubes containing dilutions from 1 in 40,000 to 1 in 2,500 of conessine were put up. There was slight inhibition with a dilution of 1 in 7,500, while dilutions of 1 in 3,000 and 1 in 2,500 definitely retarded digestion. Conessine, therefore, inhibits the activity of digestive ferments. Preparations of *kurchi* when given by the mouth should be preferably given two hours or so after meals so that digestion is as little interfered with as possible.

In intact animals under experimental conditions conessine has no effect on the intestinal volume, but it markedly stimulates the peristaltic movements of the intestine *in situ* after intravenous injection and of the isolated pieces of intestine (*see* Graphs I and II). In

Graph II.

BLOOD PRESSURE, RESPIRATION AND INTESTINAL MOVEMENTS.

2 mgms. conessine caused marked augmentation of intestinal movements (*in situ*) after adrenaline.

concentrations of 1 in 100,000, the tone of the gut is increased, while 1 in 20,000 markedly augmented the amplitude of the movements. In stronger concentrations (1 in 10,000) the organ went into a state of tonic contraction. The action of conessine therefore differs from that of emetine which produces relaxation of the gut and decreases peristaltic movements. The spleen volume was not affected but the rhythmic movements of this organ were increased.

Circulatory System.

Cold-blooded animals.—The alkaloid was given intravenously into the inferior vena cava of the frog. Large doses such as 5 mgm. produced a marked depressent action on the auriculo-ventricular bundle, the heart beats were markedly slowed and there was one beat of the ventricle to 3 to 5 beats of the auricle. Later the auricles went on beating quite independently of the ventricles, complete heart block having been established. The isolated heart of a turtle when perfused with a solution of conessine hydrochloride showed marked slowing and decrease in the amplitude of the beats.

In the mammalian heart small doses produced a temporary increase in the amplitude of both the auricular and the ventricular contractions when observed with the myocardiagraph, but this was quickly followed by depression (Graph III). The heart was also visibly slowed even after 2 mgm. given intravenously. When repeated injections were given so as to produce cumulative effects, irregularity of rhythm was noted. After a total of 15 mgm., weakening and marked slowing of both the auricular and ventricular beats were noticed; the ventricles were beating irregularly and there was a tendency for them to remain in a diastolic condition (Graph III). After a total of 30 mgm. was reached definite heart block was observed, the auricle beating twice as often or more to every ventricular beat. After 45 mgm. there was marked irregularity, the auricles showing incomplete contraction and filillary twitchings; the blood pressure fell to zero. After 50 mgm. the auricles and ventricles were seen to be beating quite independently but the contractions were feeble, hardly any blood being expelled; (Graph III).

Cardiometer experiments showed slight momentary increase in the force of heart beat as well as slowing, but this was followed by depression (Graph IV).

Perfusion of the isolated mammalian heart with 1 in 10,000 solution of conessine showed marked slowing with prolongation of diastole and irregularity of rhythm (*see* Graph V). With greater dilutions such as 1 in 50,000 and 1 in 60,000, after a latent period of about 6 to 7 minutes both the amplitude and the force of contraction were decreased and there was well marked slowing of the heart. Dilutions of 1 in 120,000 and above did not produce any result. This is interesting as injections of large doses of conessine (100 mgm. in a kitten weighing 1,500 grams) did not produce much

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

depressing action of the heart and the animal was quite well 24 hours later. The concentration of conessine in the blood would not in this case be less than 1 in 120,000.

Graph III.

MYOCARDIOGRAMS.

(1) (2) (3) (4)

(1) Shows initial stimulation of both auricle and ventricle. (2) The blood pressure has also improved in amplitude. (3) Shows marked slowing of the heart, and relaxation of ventricle. (4) Shows marked irregularity of the heart. (4) Shows feeble auricular twitchings, marked ventricular slowing due to heart block.

These experiments show that the mammalian heart is momentarily stimulated by conessine in small doses; this is followed by depression which becomes more marked as the dose is increased. The drug appears to act directly on the fibres of the auriculo-ventricular bundle causing slowing and increase of diastolic pause, arhythmia and finally heart block.• That the slowing is not due to any action on the vagal endings in the heart is seen from the fact that it occurs even after section of the vagi or paralysis of the terminations of this nerve by previous administration of atropine. Adrenalin produces its usual effect even after large doses of conessine, and conessine produces its usual effect after ergotoxin, so that the sympathetic fibres in the heart and blood vessels do not appear to be affected by this alkaloid.

Intravenous injections of conessine invariably produce a marked and persistent fall of blood pressure after a slight momentary rise. With very small doses like 0.25 mgm. to 0.5 mgm. there is a tendency to recovery after the fall, but with higher doses the fall is more or less persistent, the blood pressure never regaining its normal level. Section of the vagi or paralysis of their terminations with atropine does not alter its effects on the heart or the blood pressure. The preliminary rise of blood pressure, though slight, is quite appreciable and is seen in every case, even after injection of large doses. The smallest rise noted is 10 mm. and the highest 20 mm.; the duration

of the rise varies from 17 to 42 seconds. Perfusion of the frog's blood vessels through the aorta shows definite constriction of all the peripheral blood vessels. The kidney volume as well as the limb volume in the intact animal show a slight decrease. The preliminary rise of blood pressure is in all probability due to the vaso-constriction produced and the transient stimulation of the heart. The vaso-constriction is probably due to the direct action of the drug on the vessel walls. The subsequent fall of blood pressure is explained by the depression of the heart and the marked slowing with prolongation of diastole, due to decreased irritability and conductivity of the auriculo-ventricular bundle and the heart muscle. This action of conessine is much stronger than even that of quinidine.

Conessine has no effect whatever on the pulmonary blood pressure.

Respiratory System.

There is a preliminary stimulation, followed by depression and slowing (Graph I). With large doses, respiration becomes slow and shallow and finally stops much earlier than the heart.

Central Nervous System.

Conessine has a well marked narcotic action on frogs. Five to 15 mgm. injected into the lymph sac of an animal weighing 100 grammes produces sluggishness in a few minutes, followed by paralysis of the movements and loss of all reflexes. These amphibia become completely narcotised in 10 to 20 minutes and usually succumb if large doses have been given. In mammals narcosis is not produced, even after large doses. Conessine does not block conduction of impulses in motor nerves even after they have been allowed to remain in contact with a six per cent. solution for half an hour. A two per cent. cocaine solution under similar conditions produced complete nerve block in 5 minutes.

Local anæsthetic action.—A 5 per cent. solution dropped into the eye of a rabbit produces irritation followed by complete anæsthesia in 6 to 12 minutes. The effect lasts from 30 to 45 minutes. Weaker solutions only produce partial anæsthesia even after 15 minutes.

Summary and Conclusions.

1. Conessine has a specific action on *E. histolytica* obtained from the stools of infected kittens. It kills these organisms in mucus flakes in dilutions of 1 in 280,000 in 8 minutes in the presence of an alkali and in 18 minutes in the absence of alkali. Emetine under similar conditions kills *E. histolytica* in dilutions of 1 in 200,000, but in the absence of alkali such dilutions have no effect on this entozoon. In view of these findings it is concluded that this alkaloid may prove to be of great use in the treatment of amœbic dysentery.

2. In the case of intestinal protozoal flagellates such as *Trichomonas hominis*, conessine had little toxic effect, though on free-living flagellates such as *Bodo*, its effect was as marked as on *E. histolytica*.

3. Conessine salts (hydrochloride, hydrobromide and tartrate) can be given subcutaneously and intramuscularly. One to six per cent. solutions of such salts produce only slight local effects. No necrosis of tissues was observed.

4. The alkaloid has an inhibiting action on the activity of the digestive ferments, such as ptyalin, pepsin, and trypsin.

5. Conessine salts when given intravenously possess a marked depressing action on the tissue of the auriculo-ventricular bundle and in large doses produce irregularity, incoordination, increase of diastolic pause and heart block. Even small doses given in this manner to cats produced a marked and persistent fall of blood pressure after a preliminary transient rise. These effects were not noticed when the drug was given intramuscularly or subcutaneously, and experiments show that in dilutions of 1 in 120,000 such as would be expected to occur in the blood, it has no effect on the isolated mammalian heart. The drug could therefore be administered by these routes for therapeutic purposes, but its intravenous administration is not recommended.

6. The alkaloid has no marked effect on the central nervous system of mammals.

A Mirror of Hospital Practice.

A CASE OF SPASTIC PARAPLEGIA TREATED SUCCESSFULLY BY INJECTION OF BENIGN TERTIAN MALARIA.

By F. H. B. NORRIE, M.B., CH.M., F.R.C.S. (Eng.),
Medical Officer, The Angus Company, Ltd., P. O. Angus, Hooghly.

History.—Ram Raj, aged 40 years, Hindu male, an inhabitant of Chapra, living in Titta-ghur (Bengal) for the past 20 years, was

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

carried to the Angus Outdoor Dispensary on the 18th of June, 1926. He had syphilis some 20 years ago for which he was treated by village doctors. He has always been of active habits and was once a wrestler. The present disability commenced as a weakness in both legs some 18 months ago. For the past six months he had been unable to walk or stand, and on admission was unable to move either leg.

Physical Examination.—The patient was well nourished and of average intelligence—no atrophy of muscles. There were no sensory disturbances except in the legs, where owing to the rigidity present there was some pain when he attempted to move.

Reflexes.—Knee jerks exaggerated. Ankle clonus easily obtained. Babinski is just present. Rectus clonus present. Sphincters unaffected—potency maintained. Upper extremities, no change. Eyes, no change.

The rigidity in the legs was most marked in the morning and they had to be massaged before he could get up from his bed. All these symptoms came on gradually until the spasticity was so great that the patient had to be carried about. The Wassermann reaction of the peripheral blood was 50 per cent. positive.

Treatment.—Bismostab, beginning with ½ c. c. once weekly up to 1 c. c.; 10 injections being given. Patient intolerant to iodides in any form and in any dose. The Wassermann reaction of the peripheral blood done after 6 Bismostab injections was found negative, but that of the cerebro-spinal fluid was 25 per cent. positive.

1st July, 1926.—0.5 c. c. of a 48-hour culture of benign tertian malaria injected intravenously.

Result.—The patient had a rise of temperature on the 9th day after the injection, his peripheral blood showing *Plasmodium vivax* parasites. The fever subsided spontaneously without treatment after a few paroxysms and the peripheral blood was negative for parasites. The patient was able to stand up and walk a few paces with the help of a stick.

2nd September, 1926.—2 c. c. of whole blood from a patient (Wassermann reaction negative) suffering from benign tertian malaria was injected intravenously.

After the second injection of malaria the patient had a rise of temperature on the 5th day and had several paroxysms of fever, lasting for two weeks. The patient then discarded the stick altogether and was able to walk about the hospital ward and to help other sick patients. His cheerfulness has returned. He was put on Mist. Cinchona Febrifuge, grs. 10, t.d.s. for one week only (a total of grs. 210).

After two to three weeks exercise he was able to walk a distance of one mile without sitting down and he has since returned to his former employment.

In conclusion we would state that we do not believe that the whole of the improvement was

due to the anti-syphilitic treatment alone, for although the Wassermann reaction of the blood was negative after six Bismostab injections and there was some improvement in his general condition, this remained stationary in spite of the continuance of the anti-syphilitic treatment for nearly two months more. The real turning point in the course of the disease was noticed immediately after the injection of the second dose of malarial blood followed by its paroxysms of fever. While this patient

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was under treatment we had not heard of the treatment of spastic paraplegia by malaria, nor had we then read the paper delivered before the Royal Society of Medicine by Dr. G. de M. Rudolf in July 1926 and were in consequence in ignorance regarding the technique and dose of parasites usually given. In spite of this the happiest results attended our venture into the realm of experimental medicine.

28th September, 1926.—The photographs were taken after the patient was discharged and on this day he had come from Tittaghur and returned there in the evening.

A CASE OF QUININE INTOLERANCE.

By CH. KRISHNAMURTY, L.M.P.,
Sub-Assistant Surgeon, Sompeta, Ganjam District.

M. H., 30 years of age, male, came to me complaining of feverishness and pains all over the body. Temperature normal. A dose of a mixture of quinine (5 grains) with 2 drs. of magnesium sulphate to the oz. was given. Within about 10 minutes after he had taken the mixture he was seized with violent sneezing and blocking of the nostrils. His face was swollen and flushed and he complained of inordinate itching from head to foot. There was a severe urticarial rash all over the body. The patient was nearly mad, unable to sit or stand in one place. A few inhalations of ammonia, an injection of adrenalin and a mixture of a few doses of calcium chloride relieved him in a few hours. Externally a viscid solution of ripe tamarind (*Tamarindus indicus*) with a few copper coins soaked in it was applied. This is a recipe known to every Indian mother and I have seen it giving great relief. I am not aware of any similar preparation in the British Pharmacopœia. The patient was all right by the next day.

A CASE OF DERMATITIS EXFOLIATA CURED BY THE INJECTION OF UREA-STIBAMINE (BRAHMACHARI).

By F. H. B. NORRIE, M.B., Ch.M., F.R.C.S. (Eng.),
Medical Officer, The Angus Jute Mills,
Hooghly District, Bengal.

EKCOWRI SETT, Hindu male, aged 50, originally a grocer by profession, about 20 years ago began to feel intense itching of the scalp which was relieved by combing; this led to the shedding of profuse scales. Itching and scaling were most marked during the summer. After a lapse of two years the condition began to spread down on to the forehead, cheek, chin, neck, not sparing the inside of the ears. Gradually during the course of eight years it spread all over the body in patches, the distribution of which was irregular. The patient

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tried all manner of general and local treatment but obtained no relief. Treatment by arsenical compounds in the belief that the condition was syphilitic greatly aggravated the symptoms.

When the patient came to us the eruptions had the following characters:—

Distribution.—Most profuse on the scalp, face and neck, irregularly scattered patches over the front of the chest, legs and hands, only one small patch about the size of a 2-anna silver bit on the back.

Character of the eruptions.—Dry scales on hyperæmic bases, no discharge on peeling.

Diagnosis.—Syphilis was eliminated by the Wassermann reaction which was absolutely negative. The character of the profuse scales, the ubiquitous distribution, together with the absence of any induration and infiltration and the marked redness pointed to the diagnosis of a typical case of dermatitis exfoliata.

Treatment.—The only known drug treatment of the disease had been vinum antimoniale per mouth. The discovery of a potent pentavalent antimony salt of late years naturally suggested his line of treatment and he was submitted to a full course of Urea-Stibamine (Brahmachari). Strangely enough after a few injections the itchiness completely disappeared, the skin assumed its normal hue, the scales began to disappear and within the course of two months there was practically no sign of the disease left. Altogether he got 2.10 grammes of Urea-Stibamine.

A CASE OF INTESTINAL OBSTRUCTION.

By NARANJI M. GHELLANI,
Sub-Assistant Surgeon, Sanakhada Dispensary, Kathiawar.

THERE have recently been reported in the *Indian Medical Gazette* cases of acute intestinal obstruction ending in spontaneous recovery, such for example as that reported by Dr. Pande in the issue for March 1926. I have met with a similar case recently, details of which were as follows:—

Damodar Kalidas, a Hindu male, aged 33, was admitted to hospital on the 31st October 1926 with griping pain in the right lumbar region, radiating to the epigastrium, but not referred to the pubes, nor did it start from behind the right loin, so that renal and hepatic colic could apparently be eliminated. He was given castor oil and an injection of morphia and atropine, which relieved the symptoms.

On the 2nd November similar symptoms set in in the same site in an aggravated form. Morphia and atropine were given and an enema of soap and turpentine. This caused copious evacuations, the symptoms disappeared, and for the next fortnight the patient appeared to be doing well.

On the 20th November the same symptoms recurred with greater severity than ever. As he refused to take an enema, he was given morphia and atropine again and a sedative mixture containing belladonna was prescribed. Castor oil and an enema were given the next day, but only small evacuations—one of which contained a little blood—resulted. A tender swelling now became apparent in the appendicular region, but there was no fever, and the pulse was only 84. The belladonna mixture was continued and an ointment of belladonna and ichthyol applied locally to the abdomen, with hot fomentations.

On the 22nd hiccough and vomiting commenced, and he was given small doses of tincture of iodine orally. On the 23rd the griping pains were very severe, but he had a fair amount of sleep for the next few nights. Meantime an enormous swelling appeared along the whole of the ascending colon and across the umbilicus to the left side, and the occasional enemas which the patient permitted brought away only a few small fæcal masses. The relatives actually went to the length of having the skin over the swelling cauterised in the hope of reducing it.

The patient was now advised to go to Bombay for operation. The case appeared to be one of chronic intussusception or volvulus. The absence of fever excluded appendicitis, I had tried santonin, but no round-worms were expelled. There was neither rigidity nor acute distension of the abdomen. Visible peristalsis was now present in the abdomen.

On the 9th December Dr. C. G. Mahadevia, M.B., B.S. (Bombay), saw the patient in consultation, agreed with the diagnosis of probable chronic intussusception, and also suggested operation. In the meantime a chlorine mixture was prescribed orally—as the patient demanded medicine by the mouth—and the massage of the abdomen with the belladonna ointment persisted in. To my great surprise, however, the patient now commenced to recover, and could lie on either side in comfort, which he had not been able to do before. On the 11th December all swelling in the abdomen had cleared, and on the 18th he was back on a full diet. (During his illness he had been restricted entirely to a fluid diet.)

I do not think that the administration of Mist. Chlorinæ could have had anything to do with his recovery. In the belladonna prescription first prescribed, the dose of tincture of belladonna was gradually raised to 40 minims, and possibly this may have had some effect. The regular rubbing of the abdomen with a belladonna ointment appears to have been efficacious. The absence of fever, presence of visible peristalsis, the increasing

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

swelling over the colon, the fact that enemas only brought away small fæcal concretions, the occasional passage of a natural motion—in some instances accompanied by a little blood and mucus—all suggested chronic intestinal obstruction.

A CASE OF OPACITIES OF THE LENS OCCURRING AS A SEQUEL TO AN ATTACK OF KALA-AZAR.

By B. N. BHADURI, M.B.,

10-A, *Wellington Street, Calcutta.*

THE patient, Mr. H. S., aged 22 years, was sent to me by his family physician for failing sight of a month and a half's duration.

History of the Case.—About ten months previously he had been diagnosed as a case of kala-azar on the strength of a blood examination report. Before this diagnosis was given he had been treated for malaria with quinine and soamin for a long time without benefit. The kala-azar was treated by 22 injections of sodium antimony tartrate over a course of four months and he was then declared cured.

Two months subsequently he commenced to get frequent attacks of headache, with lacrimation and a burning sensation in both eyes, and for the past six weeks he had been suffering from failure of vision. Judging from the report from the ambulance corps, the patient's vision had been normal before his illness.

Examination.—Ocular tension normal, corneæ clear, the pupils equal, reacting to light and to convergence, the conjunctivæ and lacrimal sacs healthy.

Refraction:

R. E. D. V. 6/12—0·50 Dcy 180°=6/9 (??) and no further N. V. Su Do 50 at 12° 50 at 12".

L. E. 6/9 c—0·75 Dcy 180°=6/6 (??) Su Do 50 at 12".

Under homatropine, with oblique illumination, white streaks were seen in the cortex of the lens in both eyes. On ophthalmoscopic examination, black streaks of opacity were seen, as shewn in the attached diagram, radiating from the periphery towards the centre.

The patient's urine was subsequently examined, but was found to be normal.

The error of refraction was fully corrected. A year and a half later he was again examined and no further diminution of vision was noticed, nor any improvement. The condition of the opacities was the same.

Discussion.—The history of recent origin of the trouble, the previous report on examination that the eye was normal before illness, and the type of opacity present preclude the possibility of congenital cataract. Diabetes can be dismissed, from the general condition of the patient and the absence of sugar from the urine, though a blood-sugar examination was not done. There was no history of trauma or any kind of shock sufficient to start lental opacity. The patient's age was too early for cataract of senile type. Is it possible that it was by a mere coincidence that opacity of the lens should develop as a sequel to kala-azar?

Until we get a number of such cases of development of lental opacity in kala-azar patients, we cannot convince ourselves that the condition was caused by kala-azar; but the fact that a young man, with a normal urine report, should develop cataract after kala-azar—whilst a similar condition is sometimes seen after malaria or ankylostomiasis—urges me to publish the notes upon the case. One point worth mentioning is the very slow progress of the condition after the first examination.

Note.—We have shewn the above report to Lieut.-Col. W. V. Coppinger, D.S.O., I.M.S., Superintendent, Eye Hospital, Calcutta, who remarks that such cataracts in young persons from one cause or another are far from uncommon. They may occur in any condition of profound debility, e.g., after cholera; whilst in the case under report the stationary condition of the lesions corresponds with the improvement of the patient's condition after treatment. The condition is perhaps one of opacities of the lens, but it is essentially cataractous. The case is one of considerable interest. EDITOR—*Indian Medical Gazette.*

PERNICIOUS FORMS OF MALARIA AT SOMPETA, GANJAM DISTRICT.

By CH. KRISHNAMURTY, L.M.P.,

Sub-Assistant Surgeon, Sompeta, Ganjam District.

DURING the year 1925-26 whilst stationed in this district no less then eleven cases of pernicious malaria have come under my treatment. Sompeta is supposed to be one of the healthiest areas in the Ganjam District, yet this experience has been unique. I have previously served for two and half years in the Jeypore Agency, Madras Presidency, which is notoriously one of the worst malarial tracts in India; also for three and a half years in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Semi-Agency Tracts of the Madras Presidency, yet in neither area have I seen such severe cases. Although the onset of malaria is preceded by convulsions in many young children—and I can recall having seen as many as forty of such cases in a year and a half at Keraput—yet such prolonged periods of unconsciousness with meningeal symptoms were not encountered during my previous service in the areas mentioned. Several other cases have also been reported to me in Sompeta where treatment by indigenous practitioners has led to disastrous results.

Of the 11 cases, 8 were of cerebral type, 2 of algid type, and 1 of hyperpyrexial type. Of the 8 cases of cerebral type the age and sex distribution were as follows:—

Ages.	46	25	22	20	16	15	7	3.
Sex.	M	M	M	M	M	M	M	F.

The 2 cases of algid type were both males, and both aged about 25 years; the case of hyperpyrexial type was a female child aged about 8 years.

The following are notes on the individual cases:—

Case 1.—Male, aged 45, attacked with fever preceded by chills, and under the treatment of an indigenous physician. One night he suddenly became delirious, began to shout incoherently, leaped from his bed, and ran out of the house. He was controlled with difficulty, and had to be either held down by two or three persons or tied down. When I saw him the next morning his temperature was 102°F. and he was raving like a madman. In spite of having known me previously, he did not recognise me, and treated myself and his attendants to torrents of abuse. A calomel purge, bromides, and oral administration of quinine, with an occasional dose of morphine hypodermically brought about complete recovery in three days.

Case 2.—Daughter of *Case* 1, had a similar type of attack with convulsions and a temperature of over 105°F. She was treated on similar lines and made an uninterrupted recovery.

Case 3.—A boy aged 7, had had fever for two or three days, when he suddenly developed convulsions at about 12-30 p.m. and passed into a state of delirium, with his eyes protruding, congested, and staring, his teeth clenched, and his axillary temperature 106.4°F. Cold sponging to the head with hot sponging to the body, an injection of adrenalin with luminal sodium, were first given. After half an hour's sponging the temperature fell to 104°F., and the child could open his mouth. Calomel in butter and a soap suppository moved his bowels, whilst a bromide mixture was given every three hours. An intramuscular injection of quinine acid hydrochloride with adrenalin was given, and repeated every day for three days. He made a rapid recovery.

Case 4.—Hindu male, aged 15, with sudden pyrexia similar to that in Case 3, and he also made an uneventful recovery.

Case 5.—Hindu male, aged 16. This boy was so delirious that he ran out of the house and fell into a tank and but for those present who fished him out, he would have been drowned. He also made a complete recovery under the usual line of treatment.

Case 6.—A child 3 years of age who suddenly became rigid with convulsions and unconsciousness, and a temperature of 105°F. The child was put into a hot bath, with cold applied to the head. A glycerine enema, a calomel purge, and intramuscular quinine cured the patient.

Case 7.—Hindu male, aged 20. This patient had been in the hands of four indigenous practitioners before I was called in on the 17th day of his illness. He was restless, rolling on the floor, deeply jaundiced, constipated, and with a temperature of 101°F. A brisk calomel purge and a copious soap and turpentine enema moved his bowels, and an intravenous injection of quinine acid hydrochloride with adrenalin was given. The next morning the temperature was only 99°F., and the patient appeared to be doing well. He was put on to quinine in effervescing mixture, but by the next evening he was in a low condition, with signs and symptoms of cerebral irritation, semi-consciousness, and a failing pulse. In spite of all treatment, the patient died.

Case 8.—This was another patient who was treated by four quacks before I was called in, four hours before his death. He was groaning, with an almost imperceptible pulse, his eyes fixed and staring, and his teeth clenched. The rectal temperature was 106°F., and he was unconscious and was passing fæces and urine involuntarily. In spite of three injections of quinine and the free use of cardiac stimulants, he collapsed and died.

Case 9.—Hindu female child aged 8. This was an instance of purely hyper-pyrexial form, with the temperature 106.4°F. and the child very restless. Cold to the head, tepid sponging of the body, and quinine treatment cured the patient.

Cases 10 *and* 11.—These were both of the algid type of malaria in adult males. Both had violent vomiting and purging, with chills and rigors. They passed as many as 15 to 20 stools and vomited the same number of times within a few hours. Treatment with quinine and astringents cured both.

AN UNUSUAL FOREIGN BODY IN THE EAR.

By T. SESHACHALAM, M.R.C.S., L.R.C.P..

Assistant Surgeon, Victoria Hospital, Bangalore.

THE following case deserves to be placed on record on account of its rarity.

Abdul Rahim, a male aged 42, attended the aural department of the Victoria Hospital, Bangalore, at 9 a.m. one morning, complaining that he had been suffering from severe pain in the right ear since 4 a.m. As the ear was found to be full of cerumen, syringing was ordered. On syringing the ear a young scorpion, measuring an inch in length, came out and was found to be alive. The specimen is preserved in the museum of the Victoria Hospital.

I am greatly indebted to Dr. S. Subba Rao, Medical Officer, Victoria Hospital, Bangalore, for permission to publish this case.

AN INTERESTING CASE OF SYPHILIS.

By V. G. GOPALASAMY,

Assistant Surgeon, Karimnejer, Hyderabad Dominions.

A MALE villager aged 35 years came to me complaining of an enlarged gland in the right groin. The gland was elongated, hard, inflamed, and tender to the touch. He had a temperature of 99°F in the mornings and of 103°F in the evenings. As he gave a history of gonorrhœa, I took the bubo to be of gonorrhœal origin. External medication such as applications of belladonna and thermofuge were applied with no relief; the gland remained hard and swollen. After ten days of fever the patient developed a severe dry cough, aggravated at night. His throat was painted with Mauvel's pigment, and syrup of hypophosphites and a cough mixture given, but his condition became worse. His condition of continued fever, cough, anæmia, and debility suggested pulmonary tuberculosis, but none of the characteristic lung symptoms of that disease were present.

The patient gave a history of syphilis some six years previously, and in order to eliminate this infection I gave four intravenous injection of sulfarsenol, with potassium iodide and hydrarg. perchloride by the mouth. Within 20 days the entire condition cleared up; the bubo disappeared, and also the cough. The symptoms appear to have been entirely due to old standing syphilis.

A CASE OF TUBERCULOUS DISEASE OF THE HIP JOINT.

By KHUSHI RAM,

Assistant Surgeon, in-charge Civil Dispensary, Samrala, District Ludhiana.

A BOY aged 14 years from Dasurga district, Hoshiarpur, was brought to me for operation on the 30th August, 1926. He gave no history of previous injury to the hip joint except that he had jumped into a tank when bathing a fortnight previously and had subsequently felt pain in the hip for some days. The pain then increased and was accompanied by fever.

On examination I found a large cold abscess present near the great trochanter, with slight wasting of the thigh muscles. The joint was rigid and the gluteal fold somewhat obscured. The boy could not turn on this side and his general condition was extremely unsatisfactory. Temperature 104°F.

The next morning he was operated on under chloroform anæsthesia. On deepening the incision a large volume of tuberculous pus came out, and with a long probe I could feel that the bone was eroded with infection of the surrounding muscle tissue and synovial membrane, and destruction of the cartilage. The bone was thoroughly scraped and all caseous debris removed. A counter opening was made, the deeper portions of the wound thoroughly irrigated, and the wound packed with B.I.P.P., and dressed and a long Liston's splint applied with weight extension. A prescription containing tincture of iodine, creasote, calcium chloride and guiacol carbonate was administered orally.

There was no discharge of pus after the operation, but the wound was kept open and packed with B.I.P.P. dressings for a week. It then gradually healed up, whilst the fever disappeared by degrees.

The patient was seen by the Civil Surgeon of Ludhiana on the 20th September, who was of opinion that the case was one of tubercular hip disease and advised tuberculin injections. The patient was given these when his temperature had dropped to normal, and he left hospital cured on the 4th October, 1926. To-day (November 1926) the boy's father informs me that he is quite fit and attending school regularly. An interesting point about the case is that several medical men whom the father had consulted advised against any operation and considered that the patient would die if operated on, owing to his anæmic condition. The medical man who very kindly gave the anæsthetic for me also advised me to discontinue the operation, as the patient's condition on the table was bad. On the contrary my experience of such cases is that the sooner operation is performed, the better, as to leave the pus *in situ* may lead to final ankylosis, and its absorption is a tedious matter taking a long period of time.

A CASE OF "TYPHO-LUMBRICOSIS."

By B. P. BANERJI, M.B.,

The City Pharmacy, 285, Kalighat Road, Calcutta.

THE patient, a child aged 4 years, was first shewn to me in an unconscious state, resembling that of typhoid fever. There was low muttering delirium, subsultus tendinum, pinching at the nose and bed clothes, whilst he tried to bite anything placed in front of his mouth. The eyes were half open and rolling, the pupils widely dilated and not reacting to light. Convulsive movements also occurred at times. The pulse was very weak and the respirations hurried, the extremities cold and the fingers cyanosed: in fact the child appeared to be at death's door. There was involuntary escape of fæces, but a tendency to suppression of urine.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

I gave him at once a powder containing calomel, thymol, and sodium bicarbonate, and a mixture containing adrenalin, strophanthus, and glycothymoline. Both the liver and the spleen were enlarged, and I hesitated before prescribing a routine dose of santonin.

The parents stated that the child had had occasional attacks of malaria, had had broncho-pneumonia a month or so previously, and was always ailing, with bowel complaints and the passing of mucus and of offensive stools for the previous week.

Shortly afterwards the child became violently delirious, began to scream, had to be held down in bed, refused to take any food, and remained in this state for four days. The prescriptions given above were continued. On the third day, however, a round-worm about 6″ in length was passed and immediately the child's condition began to improve.

Throughout his whole illness the one hopeful feature of the case was that the child's condition remained afebrile, but on the fourth day the temperature rose to 100°F and remained elevated for 4 subsequent days. Once the fever had abated and the child was recovering, I administered santonin in fractional doses and five further round-worms were expelled. During his illness a bland fluid diet was prescribed with occasional rectal salines. Later on a general tonic was given and the patient made a slow but uneventful recovery.

A FATAL CASE ASSOCIATED WITH FILARIAL INFECTION.

By KISHORI MOHAN KHAN, M.B.,

Kutchery Road, Gaya.

A HINDU male adult, aged 18, was admitted to hospital suffering from fever and rigors at 5 a.m. on the 4th September, 1926, and I was first called to see the case at 1-30 a.m. on the 5th September. I found the patient lying in a restless, semi-conscious state, irritable, with a temperature of 105°F. The pulse was soft and feeble.

On examination, the spleen and liver were not enlarged, there was no neck rigidity or head retraction, Kernig's sign was negative, and the heart and lungs appeared to be normal. The patient had given a history that he had had two previous attacks of a similar fever with rigors at weekly intervals, each attack lasting for 2 days. The last of these two attacks was 7 days previous to the present one.

The blood was taken for examination, but as this was not possible at night, examination of the films was deferred till next morning. In the meantime the temperature rose to 106.8°F, and did not come down on cold sponging. As it was impossible to examine the films at night a provisional diagnosis of malignant tertian malaria was made, and an intramuscular injection of 10 grs. of quinine hydrochloride given. The temperature then dropped to 103°F, and by 5 a.m. in the morning to 100°F.

On examining the blood films the next morning, no malarial parasites could be found, but a fair number of microfilariæ were present. At 11 a.m. the patient suddenly developed all the symptoms of severe collapse, and in spite of administration of pituitrin by injection, he died at a little later. No post-mortem examination was possible.

The diagnosis is rather obscure, but a condition of septicæmia secondary to filarial infection suggests itself. During the previous 18 years of his life the patient had shewn no symptoms of filarial infection until about 15 days prior to his death.

INTRAVENOUS SODIUM IODIDE IN GOITRE.

By A. V. J. REDDI,

Sub-Assistant Surgeon, Civil and Military Police Hospital, Tiddim, Chin Hills, Burma.

I WAS an eye-witness of the fruitful experiments conducted in the Headquarters Hospital of this district during 1924 by Lieut. E. A. Davies, I.M.D., and Assistant Surgeon Dr. P. Bell, I.M.D. (now Civil Surgeon). After taking over charge of this hospital I repeated these experiments on some patients of this subdivision and obtained good results. Unfortunately the Chins here do not consider goitre a disease at all, inasmuch as it does not incapacitate them from doing their ordinary daily work, and some difficulty is experienced in obtaining a fair number of cases for carrying out the treatment. The following cases have successfully undergone the course, and presented themselves for re-examination also as originally requested:—

Case No. 1. Shewe Lian, aged 12, Chin female, a local resident and so treated as an out-patient. The goitre was of the size of a small mango and is said to be of less than one year's duration. She received six intravenous injections, one every alternate day of six grains of sodium iodide in 5 c.c. of sterilized rain water. Re-examined on 7-12-25. Tumour had disappeared completely.

Case No. 2. Kiem Sei, aged 15, Chin female, local resident and treated as an out-patient. Goitre of the size of a big marble

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and of nearly 10 months duration. Treatment the same as in case No. 1. Re-examined on 7-12-25. Swelling had disappeared completely to all appearance, but a little can be felt on pressure.

Case No. 3. Ning Lian, aged 10, Chin male, admitted as an in-patient on 16-11-25 with a soft goitre of six months duration and of the size of a walnut. Treatment the same as in case No. 1. Discharged on 29-11-25. Re-examined on 5-5-26. No trace of the gland seen.

Case No. 4. Hang Thin, aged 18, Chin female. Admitted on 16-11-25 with a goitre of five months duration and of the size of a small marble. Treatment the same as in case No. 1. Discharged on 10-5-26. The goitre disappeared completely.

Case No. 5. Gin Ching, aged 15, Chin female. Treated both as an out-patient and in-patient. The goitre was of two years duration and the size of a big lemon. Treatment the same as in case No. 1. Discharged on 30-4-26 and re-examined on 30-5-26. The tumour was reduced to nearly the size of a small marble, and may still further be reduced in a month's time.

I publish these cases to show that the introduction of small quantities of iodine into the system reduces the size of the thyroid gland in cases of recent goitre.

In conclusion I am much indebted to Lieut. E. A. Davies, I.M.D., Civil Surgeon, Chin Hill Districts, for affording me the facilities for these trials and for sanctioning permission to publish these notes.

VOMITING CAUSED BY MORPHIA: A NOTE OF WARNING.

By Y. S. ROW, L.M.P.,

Government Headquarter Hospital, Kurnool.

THE action of opium and morphine when given either orally or hypodermically is in many cases to produce a condition of irritability of the stomach and intestine. I have given it and have seen others give it with good success in many conditions due to nervous irritability of the stomach and intestine. But it is not sufficiently realised that it may induce nausea and vomiting.

Hale White in his *Materia Medica and Therapeutics* writes "With a dose of 1|2 or 3|4 gr. of morphia the skin is slightly flushed and often perspires gently, while there may be nausea or even vomiting and a transient increase of intestinal peristalsis." In another passage he writes, regarding the causation of these symptoms, "These are probably due to the morphia being excreted into the stomach and bowel and there irritating, or stimulating the neuromuscular apparatus." W. E. Dixon in his *Manual of Pharmacology* writes "A big injection of morphia may induce nausea and vomiting, and in rare cases even purging." R. Ghosh in his *Materia Medica* writes "At the outset it (opium and morphia) may sometimes cause nausea and vomiting from irritation of the gastric nerves."

From the above authorities it is evident that bigger doses of morphia may set up nausea and vomiting; but in my own experience I have known smaller doses, such as 1|4 gr. to 1|6th gr. set up nausea and vomiting, in some cases with disastrous results. One should be especially careful about giving morphia in cases after operation on the eye and abdomen, for instance. I have even seen the same thing happen when the morphia was given together with atropine, which is supposed to counteract the bad effects of the morphia.

The following two cases are illustrative;—

Case 1.—A patient admitted to a district hospital where I was working in 1920 for cataract, for which he was successfully operated on by the civil surgeon of the district. Half an hour after the operation the patient complained of very severe pain in the operated-on eye, perhaps due to the iridectomy which had been carried out. As he was very nervous and complained of the pain being intolerable, an injection of 1|6th gr. of morphia with 1|200th gr. of atropine was ordered and given. Half an hour later the patient got persistent nausea and severe vomiting set in, with the disastrous result that the eye soon filled with hæmorrhage and had to be enucleated subsequently.

Case 2.—A lady six months pregnant complained of very severe pain down the back of the thighs and along the course of the sciatic nerve, more especially on the left side. One night the pain was so severe that, in consultation with another doctor, I decided to give her morphia 1|6th gr. with 1|200th gr. of atropine hypodermically at about 2 a.m. A quarter of an hour after the injection she was much relieved of the pain and slept soundly for two hours. At 4 a.m. she was seized with severe nausea and vomiting, which lasted till noon that day. I became afraid that she would miscarry and made all arrangements to meet that emergency. Fortunately the vomiting subsided at noon, but for three days I was not satisfied that the danger of miscarriage had passed.

These are only two cases of several in which I have seen the hypodermic administration of small doses of morphia with atropine followed by nausea and vomiting. I now use morphia with the utmost caution and only in cases where subsequent vomiting may not be the cause of disaster, either directly or indirectly.

PHARMASOLS

REGD.

THE MOST EFFICIENT COLLOIDS

Truly scientific, active, reliable, economical, stable, Colloidal preparations of standard drugs for medicinal use.

Pharmasols REGD

CALCIUM

The one line of endeavour in the treatment of **TUBERCULOSIS.**

Pharmasols REGD

SULPHUR

A well-known specific in Subacute and Chronic Rheumatic Affections.

Pharmasols REGD

IODINE

The ideal form of Iodine treatment in Pneumonias, Influenza, Plague, etc.

Pharmasols REGD

TRIMINE

Remarkably useful in Eczemas and Obstinate Skin Diseases.

Pharmasols REGD

MANGANESE

May safely be termed a true specific in all Staphylococcic and Streptococcic infections and its field of usefulness is therefore very extensive.

Pharmasols REGD

FERRO-MALT CO.

Is of unquestionable value in Anæmias, Rickets and Rundown Conditions.

Don't use other Colloids until you have seen and tried Pharmasols. They are recognized as being completely in advance of everything else in the Colloidal line and these new improved Pharmasols are without a rival in quality and low prices to-day. The word Pharmasols is your guarantee that these Colloids are of immense popularity throughout India, Burma and Ceylon, unsurpassed for reliability, economy, and stability, because the methods of manufacture of these Colloids are totally different from all other so-called Colloidal preparations offered for sale in this country. Those Doctors use them who most seriously want low prices and guaranteed results. Always insist on Pharmasols.

DOCTORS

Beware of Dangerous and Fraudulent Imitations.

Read this carefully. *Times of India.*

SKILFUL IMITATION OF PRODUCTS.

FRAUD ON CHEMICAL FIRMS.

Special to "Times of India."

PARIS. (By Mail).

So cleverly did a gang of fraudulent patents medicine vendors make up and sell quantities of faked medicines to chemists in Paris and elsewhere in France that the proprietors of the patent medicines themselves when asked by the police were unable to distinguish their own products from the faked ones. The bottles, labels, printing and wrappings were all exactly imitated. Large shipments were made to Cuba and Mexico by deluded purchasers of the counterfeit medicines. Several arrests have been made but the police do not yet believe that they have caught all the men involved in the fraud which has cost reputable houses many thousands of pounds.

One of the cheated chemists with the connivance of the police set up a temporary export bureau and gave an order to the suspected persons. They duly delivered the falsified goods only to find themselves on arrival in the hands of the police.—British United Press.

SULFARSENOL AND ONLY GENUINE PACKING FOR INDIA

Imitations of SULFARSENOL of inferior quality have been put on the market by unscrupulous and cheap firms.

Beware—These fraudulent substitutes are no good for India. They do not keep fresh, they loose their activity and become dangerous toxic drugs.

For a few annas it may be a question of LIFE or DEATH for your patient. YOU may lose YOUR REPUTATION and PRESTIGE.

Insist on the only Genuine Package—it is in your own interest.

Note the only Genuine Package of

SULFARSENOL

Specially prepared for India and carrying the FULL GUARANTEE OF THE MANUFACTURERS.

If your chemist cannot supply the genuine SULFARSENOL, write to the

INDO-FRENCH DRUG Co.,

P. O. Box 458, BOMBAY.

Warning.

Genuine SULFARSENOL in the genuine packing is the only product passed by the Medical Research Committee and no other will be replaced in case of complaint.

BENZO-BISMUTH A.F.D.

THE ONLY ONE SOLUBLE, STABLE, NON-TOXIC BISMUTHIC ORGANIC SALT, OF HIGH SPIROCHÆTICIDAL POWER THAT DOES NOT CAUSE BISMUTHIC POISONING WHICH ADMINISTERED BY INTRAMUSCULAR INJECTION IS PAINLESS AND IN MANY RESPECTS SUPERIOR AND CHEAPER TO OTHER BISMUTHIC PREPARATIONS USED IN THE CURE OF SYPHILIS.

MAIN ADVANTAGES

(1) The small quantity that is injected, not exceeding 1·5 c.c.
(2) The ease with which the drug is administered either intramuscularly or subcutaneously.
(3) The painlessness after injection.
(4) The uniformity of dosage.
(5) The comparative cheapness.
(6) No liability to toxic symptoms.
(7) Complete solubility of the drug in a watery medium without leaving any particles in suspension.

In Benzo-Bismuth A.F.D the Physician has an extremely active weapon, easily handled, without danger, without risks and with the minimum of inconveniences, capable of giving results as marvellous as those previously obtained only with arsenic.

(Presented in box of 5 ampoules of Benzo-Bismuth A.F.D.)
(Accompanied by 5 tubes of Distilled Water.)

QUINARSINE A.F.D.

A very active specific against Malaria, and a regular treatment which will result in the cure of the disease, and the rapid disappearance of gametes from the blood.

In ampoules and pills.

BLENACROL A.F.D.

A very powerful Antiseptic, non-caustic, non-toxic, for urethral injections in the treatment of GONORRHOEA and its complications.

In bottles containing about 3 ozs.

MARCH.

CO-OPERATION AGAINST DISEASE.

WE have already referred to the promising work which is being done by the Bengal Co-operative Anti-Malarial Society. Such an experiment deserves the most careful study as it is only by the method of trial and error that the best results in sanitation can be obtained.

So long as the Society directed its efforts against malaria alone there was little enthusiasm; the people of Bengal are too familiar with malaria to be frightened of its ravages. Early in the history of the Society it was found that many villages owed their ill-health to kala-azar much more than to malaria and so treatment centres were opened to deal with the former disease. The results were remarkable and several centres have treated more than a thousand cases each of kala-azar in one year.

There is some evidence that kala-azar can be controlled by the treatment of all the sick and it is interesting to find that the number of attendances in village centres shows at first a rapid increase and then a steady diminution, which is attributed to the prevention of the spread of infection. It may well happen that systematic treatment such as is being carried out in Assam will prove to be the best means of controlling kala-azar, even "if and when" the silver-footed sandfly is proved to be the vector of the disease. An interesting experiment is being carried out by the Calcutta School of Tropical Medicine in a small group of heavily infected villages to observe closely what happens when every case of kala-azar in a defined area is brought under treatment as early as possible.

In Bengal the first widespread movement for the control of kala-azar was carried out, not by Government, but by the private Anti-Malaria Co-operative Society which now numbers more than a thousand branches. Some of the special features of this organisation are—

1. It owes its inception to the enterprise of Rai Bahadur Gopal Chundra Chatterji, M.B., who was formerly Sir Leonard Rogers' second-in-command. Dr. Chatterji possesses the same spirit of dogged determination as his old chief, he has met with much opposition but nothing has deterred him from carrying on his beneficient activities.

2. The Society is based on the principle of co-operation: the inhabitants of each village are induced to band themselves together to combat dirt and disease, they are made to see that the success or failure of their work depends on their own efforts, not on help from outside.

3. There is a minimum of interference with the autonomy of each centre, the chief centre supplies advice and encouragement, but leaves the management of the village centres to the local committees.

4. In addition to measures directed against malaria and kala-azar there is an organisation which deals with cholera and other epidemic diseases. In the case of cholera, just as in the case of fire, a brigade is successful in proportion to the quickness with which it gets into action, hence an effort is made to have immediate information of the outbreak of cholera and to deal with it in the most expeditious manner. It would appear that there is only one central cholera brigade with head quarters in Calcutta, evidently it is intended to make each village centre an anti-cholera brigade; when this is done it should be possible to deal with the beginnings of cholera in every locality where there is a centre, and even if the centre has not all the facilities for dealing with a large outbreak, it can render first aid and inform the public health department of the need for action.

5. Twenty tube wells have already been sunk by the Society and twelve are under construction.

6. There are 34 subsidised medical officers who are paid from Rs. 30 to Rs. 50 a month on condition that they settle down and practise in a given locality. These medical men are free to practise, but are expected to give their services to members of the Society at low fixed rates and to give free treatment to all cases of kala-azar at a suitable centre.

7. The work of cleaning tanks is one of the most important activities of the Society; this is carried out largely by enthusiastic volunteers, whose reward is the greatly improved condition of the villages in which they live.

The above is a bald outline of the activities of these societies, whose watchword is "self help."

The movement has encountered great difficulties and a good deal of opposition, but even the obstacles which have been encountered have often promoted the interests of health, for in some cases the opposition has taken the form of the establishment of rival societies, some of which are doing excellent work. Probably one of the most important influences of the Society has been to arouse a public conscience, which is the first essential for progress in public health.

The example of villages which have been cleansed and restored to health and prosperity will not be lost on other villages, and probably this is the reason why there has been such a rapid increase in the number of the local centres.

Of the total contributions made to the Society—amounting to over a lakh of rupees—no less than Rs. 70,000 has come from the Government of Bengal, while Lord Ronaldshay gave Rs. 10,000 and the Countess of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Reading Rs. 5,000. The District Board of the 24-Parganas gave Rs. 16,000, so that Dr. Chatterji has no cause to complain of apathy or indifference on the part of public authorities.

The most important point in connection with such experiments is to ensure a sound constitution so that if the guiding hand of the founder is withdrawn the whole movement may not fall to pieces. This point has not been lost sight of by Dr. Chatterji, to whom the villages of Bengal owe a deep debt of gratitude for his efforts on their behalf. The underlying principle of the Society is undoubtedly very sound, and the movement deserves the success which it has already attained.

There is a tendency to forget the vast effort which is being made by the Government Public Health agency, which has less opportunity of advertising its work in public. The work of private agencies like the Co-operative Anti-Malarial Society should help and supplement that of the Public Health Department, and it appears that this is the case in Bengal. Dr. Bentley has been one of the most enthusiastic supporters of the "rival" firm because he believes that it is only by fostering the spirit of self help that progress can be made.

ADVERTISING BY MEDICAL MEN.

THE question of advertising by medical men has been much in the public eye of late. In England the Press has been conducting a vigorous campaign against the General Medical Council because the latter disapproves of the conduct of practising physicians and surgeons who write signed articles in the lay press. The general feeling of the medical profession in England is strongly opposed to this form of publicity, not merely because it is liable to be used as an advertisement by the medical men, but also because the discussion of doubtful points in the lay press is inappropriate. There is not the slightest objection to unsigned articles, nor even to signed articles by non-practising public health officers for the purpose of instructing the public in matters of health.

In India the question of advertising by medical men has also been much to the fore of late. An Indian correspondent who wishes to remain anonymous has sent us a report of a judgment which has recently been pronounced in Karachi in connection with a law suit between two European medical men. It is not necessary to publish names, but as there is a lesson to be learned from the case it is worth while to state the broad facts as reported in the judgment. A well known medical man whom we shall call "plaintiff" sent formal notices of his intention to practise in Karachi. These appeared in several local papers, and one paper without his knowledge or consent referred to him in eulogistic terms. This paragraph should not be taken into account, as he was in no way responsible for it. His action in publishing his intention to practise and in stating his address was regarded by some of the practitioners of Karachi as being an advertisement. One of these whom we shall refer to as "defendant" called plaintiff an advertiser. Plaintiff then took an action against defendant, alleging that he had maliciously slandered him. The judgment of the court was to the effect that the press notices constituted an advertisement and that the statements made by the defendant were justified as being in the public interest. It is quite evident that both medical men considered themselves to be in the right, the unfortunate feature of the case being the washing of dirty linen in public. The lesson to be learned from this is that medical men ought to be extremely circumspect in the matter of publicity in the lay press, and that they should keep out of the law courts as far as possible.

A much more serious case is that in which a leading Indian practitioner of Calcutta has had his name struck off the register by the General Medical Council because he caused a notice to be inserted in the lay press in which he was described as an expert in the performance of the Steinach operation for rejuvenation. The merits of the case and the evidence on which he was convicted are not discussed, but assuming that a medical man causes such notices to be published in the press, his action must be regarded as being exceedingly harmful to the good name of the profession.

Then there is the case of a distinguished doctor of Calcutta who claimed to have sole proprietary rights as the manufacturer of a drug which he had discovered in the course of a research which he was carrying out with the aid of a subsidy obtained from the Indian Research Fund Association.

It is a matter of common knowledge that there is a serious degree of laxity in the matter of advertisement among the medical men of India. Large notice boards in front of the consulting rooms, in which the doctor's qualifications and distinctions are flamboyantly stated are not consistent with the dignity of the medical profession, and it is time that steps were taken for dealing with such breaches of medical ethics.

Probably the reason why so much laxity has been permitted is that the offender's fellow practitioners feel a certain degree of delicacy in reporting such breaches of etiquette, but if the medical profession in this country is to avoid losing caste it will have to purge itself of this class of offence.

The publication of lists of qualifications in telephone directories and the statement of consulting hours is rather a difficult question, but it would undoubtedly be better that nothing that savours of advertisement should appear in a publication which is in the hands of the lay public. The struggle for existence

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

among the younger members of the profession is severe and the temptations to advertise are great, but a definite stand will have to be taken, otherwise there will be a serious falling off from high standards of ethics on which the medical profession has rightly prided itself.

A Note to Readers.

The editor of the *Indian Medical Gazette* very much regrets the delay in publication of the current issue. Messrs. Thacker, Spink's press have recently been overwhelmed with work, largely in consequence of publication of annual directories; in fact the press has been working double shifts at night. The annual index for 1926, and the review of the Indian medical year, 1926, both of which went to press for inclusion in the March issue, have unfortunately had to be held over, but will be published with our issue for April 1927.

SPECIAL ARTICLES.

SOME ASPECTS OF THERAPEUTICS IN INDIA.

By R. N. CHOPRA, M.A., M.D. (Cantab.),
MAJOR, I.M.S.,
Professor of Pharmacology, Calcutta School of Tropical Medicine.

(BEING the presidential address to the Section of Medical and Veterinary Research, Fourteenth Indian Science Congress, held at Lahore in January 1927.)

LADIES AND GENTLEMEN,

I consider it my duty in the first instance to express my grateful appreciation of the great honour that you have done me in electing me to occupy the Presidential chair. Not only do I look upon it as a personal honour, but to me it is an appreciation of the institution to which it is my privilege to belong, and which has on two previous occasions during the last five sessions of this Section supplied you with a Chairman. I shall endeavour to serve you to the best of my ability and in this I shall be guided and encouraged by the example of my distinguished predecessors in this chair, some of whom I am very glad to see here to-day.

Some aspects of the subject of drug therapy which I am going to bring to your notice, are important both from a professional and economic point of view. Medicine is an ancient art, and drugs have been used as far back as history can take us. It is impossible to think of medicine as something not connected with treatment, and drugs have from the very beginning formed an integral part of treatment. Not only does a great deal of the success of medical treatment depend on the proper and correct use of drugs, but the success of surgery also has been largely dependent on the development of medicine. Surgery is, in many diseases, only a crude branch of therapy and its greatest achievements have rested on the discovery of such drugs as anæsthetics, antiseptics and disinfectants which play an all-important part in this art.

Although the use of remedies dates back from antiquity, it was only during the last half century that a study of the action of drugs has been undertaken on scientific lines, and rational explanations are now forthcoming after a long period of empiricism. The development of organic chemistry, the systematic study of the relationship of chemical constitution to the physiological action of active principles, have been instrumental in producing a large number of new drugs, some of which have very potent actions on animal tissues. Scientific study means much experimentation, and success only comes after many heart-rending disappointments. The history of materia medica shows many more failures than successes. One has only to remember how many unsuccessful compounds Paul Ehrlich had to prepare and test before he discovered such effective compounds as salvarsan and neosalvarsan.

Irrational Therapy on the Part of Practitioners.

The number of members of our profession in this country who make use of drugs in an irrational way is surprisingly large. In ancient times therapy was empirical because the ætiology and pathology of disease were not thoroughly understood, and our diagnostic methods were limited to our senses, e.g., percussion, auscultation, etc. During the last thirty years a remarkable advance has been made in these branches and drug therapy of to-day is likewise emerging from empiricism so as to be based on clearer conceptions of physiology, ætiology, and pathogenesis. Unfortunately the non-critical and indiscriminate use of drugs is prevalent in spite of this advance in our knowledge. One has only to look at most of the prescriptions written by practitioners in India to see the true state of affairs. There is a great temptation to prescribe 'shot-gun' prescriptions, as well as to advise the use of all kinds of novelties, introduced from time to time and which survive for a year or two in the drug market. Proprietary medicines, the composition of which is not known, are commonly prescribed, and different kinds of patent foods are advised, when simpler remedies would be of equal value. Many kinds of digestive ferments and glandular products are included in prescriptions and they are frequently inactive, especially in India where their proteins are so readily liable to decomposition. Vaccines and serums are injected, without due regard to their utility in the conditions under treatment. Amongst the lay public there is a craze for the administration of drugs by the intravenous or intramuscular routes, and the idea seems to have gained ground among medical men that drugs are only effective when given in this manner. Then again any drug advertised in a medical journal is considered to be useful if it is backed by testimonials. It does not seem to be realised that in addition to a large number of useful and potent drugs on the market there must be a host of others of doubtful value. Every mail from Europe brings to the practitioner in this country a number of new drugs for which the chief evidence of efficiency depends upon their trial on a few cases of a particular disease treated mostly by individuals who are not trained investigators. The majority of these so-called remedies have a very short life but during this period they often enjoy a rich harvest of patronage. They are, however, useless, and practitioners frequently try them on many of their patients without doing the least good.

Too much drugging.—There is also a tendency among practitioners to overdose their patients with drugs, and an enormous amount of money is wasted on medicines. Cases of such fevers as enteric and many other conditions for which no specific medicinal treatment exists are dosed with all sorts of complicated mixtures, when attention to diet and other forms of general treatment such as proper nursing and care of the sick and convalescent would do more good than all the drugs in the *Pharmacopœia* put together. The public in this country, more than anywhere else, have a child-like faith in medicines to cure all their ills, and judge the efficacy of a treatment from the number of medicines prescribed. Medical practitioners are often too complacent in satisfying this desire and sometimes even encourage it. When I have seen a patient and only prescribed general dietetic treatment and nursing I have often been asked "Is not the patient going to have any medicine?"

It will not be inopportune to consider the causes of this irrationalism on the part of practitioners. For only in such wise may one plan to mitigate, if not altogether to eradicate, the evil.

Medical Education in India.

The first and foremost cause of the present low status of medicine in India is the defective education in medicine generally and in pharmacology particularly, which is given to the student in this country. Two grades of medical practitioners are trained; a superior grade whose education comes to nearly the same standard as that of the students in England and America, and an

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

inferior grade (sub-assistant surgeons), who have a shorter training. The pre-medical education of both these grades is very poor. Abraham Flexner in his book on medical education says that the medical student both in America and England is poorly educated. This applies with even greater force to the student in India. In the one or two years preceding medical studies too much attention is paid to the scientific subjects, with the result that general education in subjects such as logic, sociology, psychology, history, economics, English literature, and rhetoric is neglected. The majority of the medical students in consequence are lacking in the broad outlook given by general education and the knowledge of the forces governing human interests and behaviour. Instruction in other languages such as German and French in which a large amount of scientific literature exists is not given in most colleges.

There are eight medical colleges in India turning out on an average 800 medical practitioners every year, but there are also a large number of medical schools which train many thousands of practitioners. The education of this latter class is of a lower standard and does not entitle them to registration in the United Kingdom. This kind of education is on the increase, owing to the economic conditions prevailing in the country, but the demand is incessant and so a further number of schools are being opened everywhere by private and public enterprise. In Bengal an attempt is being made and proposals have already been put forward to have a medical school in each district. A few of the institutions in the central provincial towns are well equipped and well conducted, but most of them are poorly equipped, badly staffed, and entirely unsuited to train a good class of practitioners. The result is that many of the general practitioners in India have a poor medical training. Even in the medical colleges, though the education is of a higher order, it is not entirely satisfactory. The system of imparting education is faulty. The method of selection of teachers and professors is such that most of these coveted appointments often do not go to the best available men. The provincialisation of the medical services has only made this state of affairs much worse, so far as the service men are concerned. In the old days the choice could be made from the services all over India for a chair in a particular subject, whereas now the selection is confined to a small cadre serving in the particular province in which the institution is situated. Further, there is little or no leave reserve for these particular appointments, and when an incumbent proceeds on leave the nearest available man is put in to officiate irrespective of his qualifications. The result is that at one time a teacher may be giving instruction in anatomy, at another he may find himself professor of pathology and bacteriology, and shortly after he may be installed perhaps as ophthalmologist, to be followed by his officiating in a chair of gynæcology and obstetrics. In this way it is not unusual to find a class of "universal professors" and the instruction of the students suffers for obvious reasons.

Medical Curriculum.—The medical curriculum in this country, both in the schools and the colleges, is far from being satisfactory. In countries like England and America and many European countries the curriculum has been recently overhauled and many reforms have been introduced to make it as practical as possible. The General Medical Council have carefully considered the question and Sir George Newman in his memorandum has examined every aspect of this important problem and has suggested useful improvements. The medical curriculum of to-day in India is wasteful in its method of teaching and is full of detail of all sorts representing "the conceptions of half a century ago with certain laboratory procedures superimposed." The course is overcrowded and an attempt is often made to impart to the student a lot of antiquated knowledge from text-books to the detriment of the general principles of the subject so that he only gets a very superficial knowledge. Great importance is attached to lectures and the student spends a great part of his time listening to them. Lectures based on actual experience are worth hearing, while others read from text-books can be more easily read by the student himself. Swale Vincent said that lectures are survivals from days when there were no text-books. But in India there is a scarcity of suitable text-books. In fact many of the lecturers in this country use unsuitable text-books for their lectures, which does not enhance the value of their teaching. Others give intricate dissertations, whereas they ought to present clearly and concisely the subject in hand, keeping in mind the level of the student's intelligence, many of whom can absorb only a little at a time. The great mass of theory and knowledge should be presented to the students in a carefully prepared systematic and concise form so as to enable them to grasp the essential facts and understand how to utilise the details.

Practical instruction also needs a great deal of improvement. A lot of unimportant detail is taught which is of no use to the general practitioner. Improvement in the method of instruction will result in the students learning more in a shorter time. This can only be attained by industrious work and devotion of a lot of time on the part of the instructor, and it must be done if the students are to be instructed properly. Unfortunately under the present system of medical instruction in this country this does not appear to be possible. Most of the teachers in the colleges are engaged in private practice to which they devote most of their time, and consequently the majority of them cannot give sufficient time to the proper teaching of their subject. In America whole-time professors are often employed and this is also the case with countries like Germany. In England the advantages of this system have only recently been appreciated and it has been introduced in some medical schools. The advantage of this system is that professors and teachers have not to earn a part or the whole of their livelihood by seeing patients. They are, therefore, free from the anxieties of practice and can devote themselves entirely to their subject and come into closer contact with their students. In India at present, the teachers and the students live in two entirely different worlds. The teachers have not the time to know their students, and further, owing to the large numbers that they have to teach in their classes, it is impossible for them to come into personal contact with any but the most brilliant. Furthermore, if the lecturers had more time at their disposal they could devote themselves to scientific research in their subject. The great progress made in scientific medicine in countries like America and Germany is mainly due to this scheme, and if it could be instituted in all the teaching institutions in this country the stigma that India's contribution to medical research is small would soon be removed. The teachers should be well qualified and should be given a living wage suited to their position. The idea that good men will not be forthcoming to take up these appointments under such conditions is not correct. There are many excellent men who prefer a life of study and scientific research to a life of gain, and who would be admirably suited for the posts of professors and teachers. In suggesting the introduction of whole-time professors I am fully conscious of the disadvantages of this system. Many diseases and symptoms met with in private practice are hardly ever seen in hospital practice. It has also been pointed out that the teachers learn the needs of the general practitioner as regards extension of his knowledge, etc., by being in touch with that class of practice. This object could, however, be attained by throwing open some of the clinical appointments to distinguished practitioners or by restricting the private practice to limited consultant practice in the case of a few of the senior members of the hospital staff.

Pharmacology, the science of the action of drugs, has practically no place either in the curriculum of the medical schools or of the colleges in this country. We still carry on with the old fashioned "Materia Medica" in the true sense of the word. The General Medical Council of Great Britain has laid stress on the proper teaching of this subject, and yet in very few of the medical schools and

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

colleges in India are there proper arrangements for giving practical demonstration and instruction to the students in practical pharmacology. The little instruction that is given on the theoretical side is imparted during the second and third years when the student's mind is not properly ready with the basic facts of anatomy and physiology. He is taught the therapeutic use of drugs when he does not know even the names of the diseases, much less their symptomatology, ætiology, and pathogenesis. The action of drugs on tissues, which forms the foundation of treatment of disease, is considered so unimportant that any medical man without any technical knowledge is considered proficient to teach it. The importance of proper teaching of this subject cannot be over-rated. Professor W. E. Dixon a few years ago said, "To state that the future of medicine lies in pharmacology may sound fanciful, but it is certain that the most hopeful of all signs of progress of medicine of to-day is to be found in the progress of the science of treatment." Though diagnosis is of prime importance, the patient is less interested in it than in the treatment of his disease, and pharmacology forms the basis of treatment. It tries to localize the seat of action of drugs, the mechanism of their action, and gives information about the nature of physiologic and pathologic processes. It deals with the changes produced by chemicals and physio-chemical agents, not only in healthy tissues but also in diseased ones. It is not merely a question of transferring results from isolated pieces of intestine or the uterus of animals to human beings, as is imagined by some. Circumscribed syndromes can be produced in experimental animals and the effect of therapeutic measures can be tried on them. In this way new drugs and chemicals can be thoroughly tested, not only in healthy animals but also in those in which special diseases have been induced, before they are tried on human beings. Laboratory pharmacology is the basis of research into practical therapeutics. It is responsible for the introduction of many useful compounds of arsenic, antimony, and bismuth into therapeutics. It is clearing away antiquated methods and remedies and is purifying those that remain. A sound training in pharmacology alone can make drug therapy more rational. The teaching of pharmacology in India should be improved and remodelled, and the sooner it is done the better. Only by this method is it possible to exclude the empiricism that surrounds our art. The irrational tendencies among medical practitioners are bound to go on until the teaching of pharmacology is put on a sound basis in this country. Trained pharmacologists, however, in the Indian teaching institutions are at present mainly limited to the Calcutta School of Tropical Medicine, but we are training experimental pharmacologists for various provincial governments.

The teaching of tropical medicine.—Lastly, the student is given inadequate instruction in the treatment of the diseases peculiar to the tropical and sub-tropical climates of this country. It is admitted that strictly speaking there are remarkably few tropical diseases. Most of the great scourges met with in the tropics occur in temperate climates also, and many of the dangerous diseases of temperate climates are met with in the tropics in altered forms. A study of the effects of climate, tropical sanitation and hygiene, has however a very important bearing on the understanding of disease, as met with in this country. These diseases are totally different from those described in European text-books. It is important, therefore, to emphasize tropical medicine in the curriculum of our colleges, and arrangements should be made for instruction in this subject to be fitted into our undergraduate course of studies.

Advertisement and New Drugs.

The second factor responsible for irrational drug therapy is the publicity which is given to drugs through notices in the medical and the lay press and by means of circulars broadcasted to the members of the profession. There are many manufacturing drug houses in Europe and America which prepare a large number of products and introduce them to the profession. They make sweeping claims regarding their therapeutic value, without producing very satisfactory evidence in support of their contentions. Some of these advertisements do considerable harm and they even persuade people that in order to keep well they must constantly dose themselves with the drug. They certainly encourage long distance diagnosis and treatment, and lead to the postponement of the application of proper treatment, sometimes with very bad results. The loss of time resulting from the use of ineffectual symptomatic remedies is a serious matter and there is also a great danger of drug addiction.

Professor Clark in a paper entitled "Commercial Influences in Therapeutics" very ably and forcibly brought these facts to the notice of the profession in England. He said that in that country—and the same law applies to India—there were no safeguards in the claims made for patent and proprietary medicines in advertisements which were demonstrably false. For all practical purposes the British law is powerless to prevent any person from procuring any drug or making a mixture whether potent or without any therapeutic activity whatever, so long as it does not contain a scheduled poison. He can advertise it in any terms as a cure for any disease or ailment, and recommend it by bogus testimonials under facsimile signatures of fictitious physicians, and sell it under any name he chooses on the payment of a small stamp duty, for whatever price he can persuade the public to pay for it. The therapeutic promoters occupy a position of great power. They control the lay press on account of their advertising capacity, and through it Parliament; they exercise a considerable influence over the medical press also.

In America the legislation for controlling proprietary and other drugs is very effective and the provisions of the 'Food and Drugs Act' are very comprehensive. This law lays down that in case of proprietary medicines labels or packages should not contain any statements of therapeutic or curative effects of drugs which are false or fraudulent. The use of the word 'cure or remedy' should be used only for those medicines which are 'cures or remedies' for the conditions named on the label. The placing on the label of the names of diseases is taken to imply that the medicine contained in the package is in itself a treatment for the diseases or the conditions named. This has led to the exclusion of these terms and the substitution of such expressions as 'will often relieve' or 'will aid Nature to restore,' etc. People who use these remedies on the strength of no stronger evidence than these weak assertions only have themselves to blame for the results. It is surprising, however, that even these vague and non-committal advertisements in the medical journals succeed in impressing the medical man. One reason is that on account of his genuine modesty the medical practitioner is prone to receive with undue respect any kind of plausible nonsense which appears to be scientific, and the therapeutic speculators who introduce new drugs get at the medical profession in this way. This is especially the case with biological products, which are now much in vogue. The field here is new, the mode of action of these substances is not thoroughly understood, and few general practitioners are well informed concerning them. Besides this, remarkable results sometimes follow their use which impress physicians and encourage their indiscriminate use in all sorts of conditions.

In America, the Council of Pharmacy of the American Medical Association, is serving a very useful purpose in bringing before the profession the truth concerning new proprietary preparations. This Council consists of reputed clinicians, pharmacologists, and chemists, and has a well equipped chemical laboratory. It investigates all the new preparations put on the market and carries on propaganda for the rational use of drugs. Those remedies which give promise of being more or less of value in the practice of medicine are put into its annual publication called the 'New and Non-official Remedies' or as it is briefly called 'N.N.R.' Those which are not approved by the council are dishonest or worthless preparations. Those remedies which are included in the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

N.N.R. to begin with and which are subsequently found to be useless are excluded from later editions.

New Drugs and Old.

Most new drugs are introduced into medical practice either through the agency of scientific investigation or through commerce. When they come through science, exaggerated claims as a rule are not made regarding their therapeutic value. When they come through commerce, financial considerations unfortunately often dominate the situation and exaggerated claims are not infrequently made to create a demand for them among the medical profession. The advertisements are often couched in scientific or pseudo-scientific language to impress practitioners. Commercial advertising for this reason is often misleading, though it must be admitted that many of the good class drug houses employ men with high scientific attainments, and advertise and place only such products on the market as have been properly tested. A really good drug wants no advertisement. In a very short time the most laggard of practitioners will start using it, not only for the disease in which it is efficacious but also in many other conditions in the hope that it may do good. Emetine is not only used as a cure for amœbic dysentery but is also used in the bacillary form and in many other conditions. The organic arsenicals and organic compounds of antimony are being tried in all kinds of diseases. A great many novelties however are being brought out which are not sufficiently tried. This tendency of modern medicine towards too readily accepting new remedies is to be greatly deplored. As soon as a new remedy is put on the market, practitioners hasten to prescribe it. They feel no reluctance to try new things, even though their minds are not properly acquainted with the use of old and well tried remedies whose actions are established and which are known to be of value in the treatment of diseases. They do not realize that new drugs and new methods of treatment require a long and serious study by able and experienced investigators before their beneficial effects can be established and their harmful effects discovered by treating many cases, before they can be introduced into therapeutics. The disadvantage of using new remedies is that the confidence in the old and beneficial remedies is lost. New drugs should never be allowed to come into use unless they are of unquestionable value. In the public interest they should go through proper preliminary experimentation, with adequate controls. Sir William Osler talking about the danger of new drugs and about falling under the claims of pseudo-science and commercialised empiricism, said "Give our students a first hand acquaintance with disease and give them a thorough practical knowledge of the great drugs, and we will send out independent clear headed cautious practitioners who will do their own thinking and be no longer at the mercy of meretricious literature, which has sapped our independence." It is because of his faulty training that the practitioner makes use of these old-established drugs in a perfunctory manner. Not understanding fully the action of well known and recognized remedies, and not knowing how to combine them for the treatment of disease, he takes the easiest way out and prescribes ready-made products whose action and indications for use are all made available to him by drug circulars. Proper instruction of the student is the most effective weapon against the evil of falling into the hands of therapeutic speculators. The intelligent selection and proper administration of therapeutic remedies depend essentially upon skilled teaching. Drugs should be given with an object, and it is the duty of the physician to verify at each stage whether this object is gained or not. If treatment is conducted in the same way as scientific investigation, irrationalism will disappear from our therapy.

Control of Therapeutic Agents in the Market.

It frequently happens that a practitioner seeks the new drugs because he has lost confidence in the old ones. This is due to the fact that a large number of drugs which appear for sale on the market in this country have not always the therapeutic activity which they are alleged to have. The factor of climate is of great importance; the high atmospheric temperature combined with a high degree of humidity produce deterioration of drugs during storage. For the last few years I have been engaged in examining by chemical and biological assay many preparations of potent drugs on the market, both those manufactured by the drug houses in India, and those imported into India.

(1) Those manufactured in this country are subjected to no control whatever by the State to see that the quality of the preparations is up to the standard laid down in the pharmacopœia. I have tested a number of such preparations and have found them to vary a great deal in their strength. In some cases the preparations came up to the prescribed standard, but very often they were below the average, and sometimes quite inert and therefore useless for therapeutic purposes. This is specially the case with preparations made from such drugs as digitalis, strophanthus, squills, ergot, cannabis indica, etc. These preparations, which can only be assayed by biological methods, are put on the market without their potency ever having been tested.

There is no law to prevent this. There is, so far as I know, only one firm of manufacturing chemists in India who get their products biologically assayed before putting them on the market. The shortcomings of biological assay are admitted, and we know that it is only accurate within 20 per cent. and the margin of error is wide. But from the point of view of the practitioner some form of standardization is necessary for all potent drugs, and more particularly for those drugs of which the active principles cannot be isolated, because it is especially in these that there is danger of obtaining inactive products. Not only are galenicals and other pharmacopœal preparations manufactured by Indian firms, but attempts are being made to prepare some of the biological products such as gland extracts, vaccines and serums, and some of these have been put on the market. Besides these, a number of potent organic compounds of antimony have been introduced by some manufacturing firms in Calcutta and are being largely given intravenously by practitioners. No control whatever is exercised by the State over these potent compounds with a view to see that different batches of these manufactured products are chemically the same and that their toxicity has not varied. In the case of all organic arsenical and antimonial preparations introduced into therapeutics in America and the European countries a strict and severe test is enforced.

(2) With regard to the imported drugs, which form by far the largest proportion of drugs used in India, most of them are manufactured by reputed firms who employ a competent staff of chemists and pharmacologists to standardise them. The climatic conditions however in this country have to be taken into consideration. A few years ago my laboratory tested nearly a hundred preparations of digitalis made by reputed firms and found that most of these had deteriorated to the extent of 30 to 40 per cent. within a few months of their arrival in India. Some drugs such as thyroid extract, adrenalin, pituitrin, etc., are similarly affected. Several batches of old tablets of pituitrin and adrenalin and some containing potent alkaloids which we tested had appreciably deteriorated in quality. The keeping properties of organic arsenicals and a number of other potent remedies when exposed to tropical climates, still remain to be worked out. Control of these products on the market is therefore of prime importance.

Therapeutic Substances Act for India.

In the United States of America the Government controls the remedial agents by means of an inter-state commerce clause of the constitution. Under this Act the "Food and Drugs Act" is enforced by the Bureau of Chemistry of the Department of Agriculture, while the sale of biological products such as serums, vaccines, etc, is controlled by the Public Health Service. Not only is control exercised over all drugs, serums, etc., that are meant for home consumption, but all substances belonging to this class which are imported or exported are also governed by the Act. The Act is designed to secure

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

truthful names and reliable statements for all the remedial agents and is divided into two parts.

Part 1 of the Act is concerned principally with preparations primarily designed for the use of the laity direct, and Part II applies to medicines ordinarily prescribed by physicians. This Act ensures that the purchaser, whether a physician or a layman, secures an honest product. It means that pharmacopœal preparations must come up to the standards laid down in the *United States Pharmacopœia*, failing which the manufacturers will be prosecuted. In the case of patent medicines the law requires that only those claims should be made which can be substantiated, and in this way it controls exaggerated claims and misleading and false advertisements. Standards are provided for most of the biological products. In the case of preparations for which tests of standards are incomplete, the samples are sent to the Government Laboratory with a copy of the record of the maker's tests and these are repeated and the preparations are finally passed for sale or rejected. The toxicity of each batch of organic arsenical products is tested before it is allowed to be sold. No license is granted to any firm until the licensing authority is satisfied that the personnel and equipment of the firm is qualitatively and quantitatively efficient for the purpose for which the license is sought. In addition to this licensing system, samples of finished products are bought in the open market and are tested by officers of the Government with regard to their purity and potency. By these activities a constant control is kept over these drugs, and the postal authorities are responsible for the prevention of frauds and exploitation through the post. In England the 'Therapeutic Substances Act'—corresponding to the American Food and Drugs Act'—was introduced only recently, but its terms are not so comprehensive. This Act controls the quality and authenticity of such therapeutic substances as cannot be tested adequately by direct chemical methods. These are divided into three groups. *Group I* consists of biological products, such as vaccines, toxins, and antiserums. *Group II* includes substances such as organic arsenicals and antimonials. *Group III* is formed of insulin and other gland products. The manufacture of these substances is carried out by properly licensed firms who conform to the standard of strength and purity laid down by an appointed committee.

In India there are no safeguards whatsoever against manufacturing, advertising, and selling to the public therapeutic products of any kind, whether potent or inert, effective or ineffective. The result is that a large number of medicines, both proprietary and otherwise, which are presented for sale in the market, fall far below the standard. Lately a good deal of interest has been taken in this subject and in a lecture to the Rotary Club at Calcutta the subject was brought up for discussion. The speaker suggested that legislation on the lines of the British Food and Drugs Act should be passed in India as a means of protection against the indigenous production of patent and other medicines. At present, while in other countries regulations regarding the preparation and sale of medicines are very strict, no standard whatever of any kind is imposed in India. Many manufacturers in this country produce articles which have only a slight resemblance to the standard or genuine articles, and therefore firms anxious to produce only reputable goods cannot compete with them. The excise authorities instituted an enquiry into the causes of falling off of sale of rectified spirits, and found that in many cases alcohol was not being used in the quantities necessary to produce the standard articles. The medicinal or therapeutic value of the preparations may be negligible and the consumer has no guarantee that the standard of activity is being maintained. Large quantities of medicines are sold in tablet form, offering an excellent opportunity for deception, and an example was given wherein 5-grain tablets of quinine consisted of only one grain of quinine and four grains of starch or other inert matter. Essential oils such as sandal wood oil, cinnamon oil, etc., and preparations such as vinum ipecacuanhæ have many inferior substitutes on the market.

Such being the case, is it at all surprising that the profession should lose confidence in these remedies? And it is this want of confidence which leads the physician to try anything new that reaches him by means of advertisement and drug circulars. The question of protection from these medicinal frauds touches not only the physicians but the whole of the public, and an Act on the lines of the British Act, or better still on the lines of the American Act, is the only possible remedy.

Control of Dangerous and Narcotic Drugs.

In many civilised countries dangerous drugs, including narcotic drugs, are controlled by the State. In Great Britain recently as the result of an enquiry by a Committee, regulations concerning the manufacture, sale, and even professional use of narcotic drugs have been extended and re-enforced, and many drugs such as barbituric acid derivatives like veronal have been included in the schedule. Addiction to such drugs as morphine and heroin, according to this Committee, is rare in England now owing to enforcement of the Dangerous Drugs Act which makes it very difficult for the addicts to get these drugs except through a medical practitioner. In India there is little or no control over the sale of these drugs. Though drugs like morphine and cocaine are not supplied except by a prescription from a physician, opium and cannabis indica are sold to any one who goes to the shops licensed by the State, and addiction to these drugs has increased during the last decade. Large quantities of cocaine are also smuggled into the country and this most vicious of all drug habits is prevalent among a certain class of the population in India. Recently some interest has been taken in the problem of the opium habit by public bodies such as the Indian National Congress, and the Government has been urged to control the production and sale of opium. The sale of all narcotic drugs needs to be brought under more strict control. In countries like America drug addicts are registered and are regarded as wilfully vicious individuals; they are notified to the authorities before drugs can be supplied to them. Legislation on similar lines which would not only make it very difficult for the general public to buy these drugs but would also brand the addict with a stigma is the only means to prevent the spread of drug habits.

Need for Central Organisation. Therapeutic Research.

The control of therapeutic remedies on the market can be properly effected only if there is a central organisation, similar to that existing in the United States or like the Medical Research Council in England. Things are so complicated and specialised nowadays that the investigation of details is beyond the power of any one individual. The chemists, the pharmacologists, the physiologists, and the biochemists must work in co-operation with each other and should have all the facilities necessary for their work. This can only be effectually done if there is a central organisation under the control of the State, capable of testing substances from every point of view. This central organisation will not only help in the control of the therapeutic agents on the market, but having competent men representing all branches of medicine on its staff, it will conduct therapeutic and other researches on the important problems which are peculiar to India. It should be situated in a large centre where ample clinical material is available. The central organisation could have ramifications spread all over the country, so that problems peculiar to different parts of the country could be dealt with efficiently. Our problems are numerous, immense, and unworked, and if such an organisation comes into existence a tremendous impetus would be given to medical research in this country. It is about time that a beginning on some such lines was made. Until quite recently the idea of medical research in this country was mainly confined to bacteriology and to the closely allied branches of medicine; in fact the Medical Research Department under the Government of India was known by the name of the Bacteriological Department, and most of the appointments under it even now are filled by bacteriologists, protozoologists, and entomologists. Research should be

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

looked upon from a much broader point of view. We should have research workers in all branches of medicine in order to examine every aspect of our medical problems. The importance of medical research does not appear to be sufficiently appreciated by the public in India. It is not realized that the foundations of medicine and its application are based on research, and that the protection and advancement of research is the primary duty of the State. Sir Ronald Ross in a lecture recently said that to human beings medical discovery was the most important of all kinds of discovery and the amount of public attention given to it was disproportionately small. He said that in England the total amount provided for medical research worked out at about one penny per head of population per year, and tremendous results were expected by the public for this small expenditure. The contribution of the State towards medical research in India is very small indeed considering its size and its population. Medical research has suffered for want of means. It requires expensive laboratories, costly apparatus, and a staff of competent workers who have to be well paid, but the statesmen who are responsible for the public purse somehow seem to be reluctant to spend money on it. The short-sightedness of this policy has at last been realized in England. During the last few years, the United Kingdom has been spending £140,000 a year on medical research, and the immense value of the work done and the benefits which the public have received from it are now being appreciated. The future of medicine in India depends on ample provision being made for the vigorous prosecution of research. Its benefits will soon be appreciated. State recognition of research will also stimulate voluntary endowment. On this also depends the improvement of medical education and the turning out of a good type of practitioner. The spirit of research should be inculcated in all the teaching institutions, as there is no doubt that the best teaching can only be carried out in an atmosphere of research, and the best students can be turned out only by men engaged in research work. Research and teaching are intimately connected.

The advantages of such an organisation would be very great indeed and the resulting economic gain to the country would be enormous. There is a large number of problems which challenge the medical research worker and which might be worked out to the great advantage of the people. The standardization of treatment with such remedies as quinine, emetine, antimony, and arsenic compounds, etc., for diseases prevalent here will not only be of importance from a medical but also from the economic point of view. If maximum and minimum effective doses of such drugs, and maximum and minimum periods of their administration are worked out by a properly constituted body of experts a lot of waste could be avoided in the use of these drugs. The saving effected would more than pay for the cost of upkeep of such an institution. Even for such a prevalent disease as malaria no standard treatment has so far been worked out, and the amount of the expensive cinchona alkaloids which are wasted on account of the great disparity of doses is enormous. Major Sinton's work in this connection is most valuable, but being single-handed he can only investigate one aspect of the problem at a time. Here is a field of medical research where co-operation might considerably facilitate a most useful inquiry. The State alone could give facilities for work with an ideal population under control such as the army, and non-infective sites such as hill stations where experiments could be properly conducted. I do not wish to go into details of the many important problems peculiar to India which remain unsolved, but I think that it may not be out of place to mention some of them to show their importance.

Filariasis is prevalent, not only along the sea coast but some hundreds of miles inland. Although a complete survey has not been made for the whole of India, the work done at the Calcutta School of Tropical Medicine shows that in eight districts in Bengal the population is affected to the extent of 4 to 16 per cent; in Behar, Orissa, and Chota Nagpur the figures are much higher, going up to 27 per cent. Most of the sea coast districts of Madras and Malabar are heavily infected. A large portion of the population of these areas is incapacitated from this disease every year. Yet a perusal of the literature on the subject shows that very little work has been systematically undertaken to find out an effective treatment for this disease. Another allied disease which is also responsible for a lot of incapacity in Central India and Rajputana is *dracontiasis* or guinea-worm infection. We are still where we were half a century ago regarding its treatment, and with the exception of the work done by Dr. Hamilton Fairley the problem has not been worked out. A disease of great importance is *kala-azar*, which has been, and is still taking a very heavy toll from the inhabitants of Assam and Bengal. This is one of the few Indian diseases on which systematic work has been undertaken, and it affords an example of what can be done by properly conducted research work. During the last decade the mortality rate of 90 per cent. caused by this disease has been changed into a cure rate of 90 per cent. by the development of its treatment with pentavalent compounds of antimony. Many questions, however, in connection with its transmission, prevention, etc., still remain unsolved.

Ringworm is one of the most widely prevalent of skin diseases in all parts of India and it is responsible for a lot of incapacity. Major Acton, during the past year, has been engaged in the differentiation of its species and the recognition of the pathological lesions produced in man by this disease, but with this exception no attention has been paid to this important source of incapacity. A pest which regularly visits Bengal every year about the end of the rainy season and of which we have had a big outbreak last year is epidemic dropsy. It is responsible for much incapacity and has a fairly high rate of mortality, but we are still not quite clear about its ætiology, pathogenesis, and treatment, though the investigations made in connection with it at the Calcutta School of Tropical Medicine during the last few years have thrown a good deal of light on it. A group of conditions including infective conjunctivitis, infective granulomata, and tropical ulcers, though not serious to life, are responsible for much disability and do considerable harm to the population; they form a practically unexplored field. Pernicious anæmia of pregnancy, osteomalacia, and infantile cirrhosis are common in some of the large towns of India. Dengue and a number of fevers of short duration are prevalent, but their ætiology is not solved. The post-dysenteric conditions such as asthenic diarrhœa, chronic peritonitis, and cirrhosis of the liver are prevalent but we have little knowledge concerning their pathogenesis or treatment. Tuberculosis is spreading in many parts of India and so far nothing has been done to find out the reason for this increase and the measures which can be taken to prevent it. Drug addiction has also increased since the war.

Training of Research Workers.

Such are some of the problems peculiar to our country that can be tackled by experts at a central institution or in the areas affected by the diseases concerned. Such a body alone can make concentrated efforts and attack them from every point of view. Considering the immensity and importance of these problems to the welfare of the people, it is obvious that the State would be quite justified in spending money to give facilities for their investigation. The first great need is for a fully staffed and thorough equipped central institution in which workers can be trained and from which investigators can be sent out to investigate diseases in the places where they occur. In addition to this the local governments should be encouraged to provide research laboratories for work on the special diseases of each province. Medical research to-day is not a single-man show; at every stage one needs the valuable assistance of colleagues of real worth. Without their co-operation, progress is bound to be small. Unfortunately we have at present very few such trained workers available in India, either in the services or outside, for the simple reason that there is no proper

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

training ground for them. There are a number of enthusiastic young men educated in the Indian as well as the British and American universities who take a keen interest in this kind of work, but they cannot take it up for lack of opportunities. It is essential that provision be made for the training of young workers and for ensuring a prospect of a decent livelihood for them in research. The result of the present state of affairs is that when a new line of research is to be started there is very great difficulty in finding suitable men for it and a worker from outside has to be imported on a very high salary. As often as not funds do not permit of this, and the work is dropped entirely. The central institution could serve as a training ground for research workers. One of the duties of the experts on its staff should be to train suitable young men for research in different branches of medicine so that they would be available for work on different problems.

Medical, Veterinary, and Allied Sciences.

And last but not the least, I would like to bring to your notice the necessity for closer co-operation with the sister science of veterinary medicine and with such allied sciences as zoology and botany. The problems of the veterinarians are much the same as ours, and zoologists and botanists can render us considerable help in connection with the transmission and spread of disease and its pathogenesis. For nearly thirty-five years Clifford Allbut advocated the importance of the study of comparative medicine. His ambition was to found a school of research in animal and plant pathology in Cambridge. A chair of animal pathology was established a few years ago, and the beginning of a great school of comparative medicine and pathology has already been made in that university. The tendency of the medical and veterinary professions to work in water-tight compartments is to be greatly deplored. Co-operation between the two professions can be of immense use in working out some of the obscure problems with which we are confronted in India. A section of comparative medicine was started a couple of years ago in connection with the Royal Society of Medicine, and Mr. Frederic Hobday in his presidential address said "The foundation of our present position in the administration of anæsthetics, the splendid safety of our present day surgery, the study of therapeutics and pathology, even medicine itself, all had the principal part of their pioneer work done upon animal patients, before being applied to the human being." Those engaged in resarch work can fully appreciate the significance of the remark. In our every day experimental work on animals many points arise in which veterinarians could help us with their knowledge of animal anatomy, physiology, pathology, etc., to correctly interpret our observations and apply them to the service of man. Medical men and veterinarians are alike intimately concerned in pathogenic bacteria and protozoa, and there are many diseases in this country common to both men and animals. Rabies, Malta fever, anthrax, intestinal parasites, rinderpest, bovine tuberculosis, etc., and many skin diseases are transmissible from animals to man. A combined investigation of such problems would be of very great value to both and would not only help to alleviate the suffering of humanity but would also benefit the animal wealth and agricultural resources of this country.

I may urge in conclusion that my plea for a central research institution does not proceed from any class or service motives. I regard research in medicine as of prime importance, and for such research to be effective co-ordination and co-operation are essential. Such a growth cannot be achieved by private or individual effort; the collective resources of the nation must pull together to attain the desired harmony and progress. I have pleaded for State help, for I consider that in a vast country like ours, where perhaps socialised institutions are the only effective agencies, a problem of such magnitude and importance cannot otherwise be solved. A State exists for the good of the people, and what greater service is there than a growth in the health and vigour of the races concerned?

"HE CEASED TO BE A DOCTOR"

By W. H. OGILVIE, C.B., C.M.G., M.B.,
MAJOR-GENERAL, I.M.S.,
Director of Medical Services, India.

I HAVE lately been in conversation with one or two officers of the I.M.S. occupying important executive appointments on the civil side of the Service. They were well versed in the curative side of the profession and one at least had seen a good deal of active service during the great war and had served in it with credit. The course of conversation led them on to express regrets at the waste of their curative talents during the war; to estimate the worth of all officers of the medical services almost entirely by their skill in curative treatment; and to the statement that the majority of officers of the Medical Services in military administrative employ had "ceased to be doctors."

I had thought that this view of the position of the science and art of medicine in relation to the Army had disappeared after the war. The knowledge that it still exists is a cause of somewhat bitter reflection on the misapprehension of the rôle of military medical officers. While acknowledging the possible accuracy of "Qui s'excuse s'accuse" I feel it incumbent on me to lay before my brother officers another aspect of the question.

A good statement of some of the points will be found in *The Journal of the Royal Army Medical Corps,* Vol. XLIV, No. 4, for April 1925, in an article by Major H. S. Blackmore, O.B.E., R.A.M.C., entitled "Overcome soldiers accustomed only to the usages of the past." This publication is possibly not seen by some I.M.S. officers, and in any case the apologia here set forth runs on lines not identical with those of the article referred to. One of the reasons for referring to the article is the idea contained in it of grouping all the activities of preventive medicine, surgery, curative medicine, and all cognate arts and sciences under the heading "Health Services." In spite of any academic criticism of the words they remain a convenient formula for expressing the idea of preventing ill-health and of restoring health when lost by any cause whatsoever—disease or accident. This expression is therefore used in this article with this meaning.

The point of view now combated is founded on the narrow conception that a "doctor" is one concerned only with the comfort and cure of the individual patient. The function of one trained in Health Service who joins the Army is that of a medical soldier, and consists in helping to "win the war." He does this by:—

(1) Preventing as far as possible inefficiency due to preventable causes.

(2) Lessening unpreventable inefficiency by the collection, removal and treatment of casualties due to battle and disease.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

He effects this purpose by:

(1) A knowledge of tactics. By this he can appreciate the military problem and can make the best use of the "Medical Arm" to contribute to the success of the Commander's plan.

(2) A knowledge of military organisation and administration whereby he can make the best use of all the means at the disposal of the "Medical Arm."

A knowledge of tactics and organisation when applied to health matters is obviously of little use without a knowledge of the science of health. Therefore the "Medical Arm" can only be run by those acquainted with this science, i.e., the medical profession. Conversely, those of the medical profession who serve in the Army can only achieve their end by a study of tactics and organisation, thereby becoming medical soldiers.

This view can be illustrated by imagining the alternatives:—One is the placing and moving about in the war zone of civilian practitioners ignorant of tactics and military organisation, and dependent for these on attached officers of half a dozen branches of the army—General Staff, "A," "Q," S. & T., Ordnance and Veterinary.

The other is the establishment of a Service trained in health, tactics and organisation, and which can apply a knowledge of health to military problems.

The first alternative is on the face of it unworkable and has been proved so by experience in the past. The second has proved its worth whenever tried, and never more so than in the great war. The deduction seems inevitable that "the Medical Arm" of the fighting services can only work satisfactorily if the individuals composing it have a thorough knowledge of the science of health—both preventative and curative. The fact that this knowledge is applied to a special end cannot justify the opinion that it does not exist.

Has the medical soldier really "ceased to be a doctor"?

THE INTERCHANGE OF HEALTH PERSONNEL IN JAPAN UNDER THE AUSPICES OF THE LEAGUE OF NATIONS.

A Report by F. P. MACKIE, O.B.E.,
LIEUTENANT-COLONEL, I.M.S.,
(*Calcutta. Government of India, Central Publication Branch*, 1926).

(THIS report on Japanese hospitals is of great interest, giving as it does the impressions formed by an expert who has an intimate knowledge of European and Indian hospitals. We give a few extracts which will enable our readers to form an idea of the conditions which prevail in Japan.)

The Japanese Red Cross Hospital in Tokyo.—Is primarily intended for soldiers and sailors in war time but during peace time it is used largely as a civilian hospital.

It is largely used as a training ground for relief personnel and also for nurses both for work in the hospital and for private cases outside.

It is a substantial building in European style and has a very well equipped outdoor clinic of the most up-to-date pattern. There are special departments for medicine, surgery, diseases of the eye, ear, nose and throat, obstetrics and gynæcology, pediatrics, skin, dental, hydro-therapy and physical treatment and also full laboratory and other scientific departments.

All these departments, including the minor ones such as dental and hydro-therapy, are remarkably well equipped and up-to-date and this applies to all the larger hospitals I visited.

There are 365 beds in this hospital and all but 93 of these are for paying patients. This is a feature of most of the hospitals in Japan, that all patients who can afford to pay anything do so and so there are large numbers of private wards generally of three grades, first, second and third, according to the paying capacity of the patients. In some hospitals also a small fee is charged to out-patients and from these sources a considerable proportion of the running expenses of the institution is met.

During 1924, 34,142 out-patients were seen and of these 30,699 were paying patients and 3,443 were free, and for in-patients the figures were 2,220, and 394 respectively. This shews the extent to which the paying system holds in this institution.

The staff included 74 doctors for 365 beds which strikes one as being very high, one doctor to every five beds and to 461 out-patients.

The nursing staff numbers 95, i.e., under four beds to a nurse.

Osaka is the biggest and wealthiest city in Japan and is the great industrial centre and it is not surprising to find here the biggest and best equipped hospital we had yet seen.

It is a hospital which would be a credit to any great city in Europe or America.

It contains 500 beds and can treat 500 out-patients daily as indeed it does. Besides the usual departments for medicine, surgery, and diseases of women it has clinics for diseases of the eye, ear, nose and throat, children, skin diseases, X-Ray rooms, physical culture and hydro-therapy, and nervous disorders departments. The roof is laid out in a beautiful manner with typical Japanese landscape gardens, dwarf trees, lakes for lotus plants and goldfish, and part of the roof is enclosed as a solarium for children and for early cases of tuberculosis.

There are large numbers of private and semi-private wards where paying patients are admitted and these rooms vary from about ten rupees to about two rupees daily according to the means of the patient. One-third of the hospital is given over to the paying side and in the other 2|3rds treatment is free though in some cases food is paid for.

The medical staff is not so large, being on paper only 21 giving an average of about 24 beds per doctor and with a nursing staff of 130, an average of nearly 4 beds to a nurse.

The equipment of the laboratories and other scientific departments is lavish, the most costly types of equipment being provided.

Remarks on the General Hospitals.—The hospitals we were privileged to inspect were models of their kind and it is evident in the construction of new hospitals that the most up-to-date models are being taken. Money appears to be lavished on equipment, for instance in one of the hospital laboratories for routine work I counted seven microtomes mostly of the most expensive types, and this sort of equipment seems to be the prevailing note. The buildings and wards and the furniture thereof were all of European type, Lawson Tait beds, high lockers, etc., quite different from the construction of houses and the furnishing of Japanese homes. The system of hospital charity is not so marked a feature as in Europe and elsewhere in the East. Here every one is expected to pay something, and to be a charity patient is the exception.

Even when treatment is free small charges are made for food.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

This system is a good one as it induces the spirit of self-help and reduces pauperisation to a minimum.

Another point which struck me was the magnitude of the staff: what with the senior doctors, the junior assistants, the internès, the students, the nurses and the probationers, the wards and more so the out-patient clinics seemed to be much overstaffed and appeared in very great contrast to Indian hospitals which are generally disgracefully understaffed.

The medical profession in Japan is considered to be a very honourable one and young men seek entry to it eagerly. Moreover it is regarded highly by the State and many of the highest offices are open to it. Money is given freely for its necessities and the result is a quickly rising level of national health.

Most of the hospitals are open freely to post-graduate workers and almost all have training schools for nurses who are extending their work outside the hospitals in all directions.

Tokyo Municipal Sanatorium for Tuberculosis.—There are six tuberculosis sanitaria in the country of which the one we saw at Tokyo is much the largest having 800 beds, Osaka with 350 beds and the other four having each 100 beds.

When we visited the Tokyo institution there were 535 male patients and 216 females. The percentage of all forms of tuberculosis in Tokyo is 37.6 per 1,000 and of pulmonary 26.2 per 1,000.

The method of sterilizing sputum by boiling with live steam is good and so are the details for collecting this infective discharge both inside and outside the hospital.

The department of helio-therapy and X-rays was very good and up-to-date and the results are very satisfactory. Artificial pneumothorax is resorted to in a few cases and there are well devised pressure chambers for graduated lung distension in such cases.

There are excellent laboratories and autopsy rooms here and as in other hospitals in this country the most is made out of any pathological material obtainable.

This sanatarium besides being of high standard from the medical aspect shewed in a high degree the best spirit of social service.

They send out a member of their service staff to the houses of patients who are known to have tuberculosis and cannot for some reason be admitted for treatment, and in the same way they follow up the cases discharged and attend not only to their disease but also to their general welfare.

The patients in the hospital seemed very comfortable and happy and recreation or light work was found for all but the severe cases.

The majority were busy doing light work in the garden or helping the nurses in the wards. There was a spirit of peace and hopefulness amongst the patients which is partly due to the fact that they are not hustled out when they begin to improve but are allowed to remain indefinitely if they do not improve or until they are well enough to return safely to the homes.

The Prefectural Mental Hospital of Tokyo.—We visited the above named asylum and found it simple in construction but efficiently administered.

It is run on the non-restraint system and no form of punishment is given. The continuous warm bath treatment is given to noisy and restless patients and there are padded cells for the violent and dangerous class. The commonest forms of insanity are dementia precox 1,351, general paresis, 851 and maniac depressive insanity, 263 during the last five years. As many patients as possible are given employment and the farms, gardens and building operations are almost entirely carried on by the patients. The pathological material is made good use of and the museum contained many excellent preparations and there was a good laboratory for research. Some cases of G. P. I. have been treated with active malaria with good results.

Adequate measures are being taken to deal with the prevention and treatment of leprosy.

It appears that leprosy is on the decline which may be the result of the active measures which have been taken during the last decade.

There are five leper asylums in Japan of which the largest is the one which we visited in Tokyo which has 750 beds, whilst the others have 160, 400, 270, and 500 respectively.

It is estimated that there are 10,000 pauper lepers in all Japan and a scheme is on foot to provide sanatarium accommodation for the large majority of these.

Zensei Leper Asylum in Tokyo.—There is accommodation for 750 and there were actually 721 the day we visited it, of which 125 were females.

Wandering beggars are taken up by the police and sent here, and there are very few escapes though the light fencing affords easy escape.

The fact is that the patients are so well treated that they prefer to remain in the asylum and come from distances to claim admission.

Better class patients who do not care to leave their homes have to undergo supervision by the police and have to conform their lives so as to be as little danger to the healthy as possible.

When asylum patients improve markedly they are allowed on parole but it seems that they almost invariably relapse and no patient has ever been discharged as *cured*.

Vasectomy is done with the permission of the patient, 200 have been performed in 10 years. Women admitted pregnant are allowed to keep the child for a year and then it must be handed over to foster parents outside. About 30 children have been born in the asylum in the last 16 years and none has developed leprosy.

What struck one most was the freedom and absence of restraint so that the asylum was much more like a hospital or a sanatarium than a barrack or a prison as is sometimes the case in India.

Nearly all the farm and garden and building work was done by the patients and for these duties they receive small sums in payment for purchasing extras. They do not use current coin but have a special currency which is only valid for use in the asylum.

Great attention is paid to their recreations and they have books, games, radio sets, amateur theatricals and concerts by outside artists. Religious exercises are much encouraged and are very welcome to these sufferers and all castes and creeds receive equal encouragement. There are schools for the young lepers.

In short this asylum was a good example of a mixture of sound medical treatment with high grade social service, tinctured with religion in its most practical form.

The medical side was as good as could be wished, there was a good museum and adequate use was made of the pathological material, there were a number of excellent casts of cases in all stages of the disease and these were produced to compare with the results of treatment thus giving life-like contrasts.

This is one of the institutions I should like to transfer bodily to India to serve as a model.

Research Laboratories.

The number and high standard of research laboratories is one of the salient features of Japanese medical organisation, and in addition to the well equipped laboratories which are always found to be connected with the big hospitals, as well as the clinical rooms which are attached to each department, there are a number of purely research institutes some of which we visited.

The Kitasato Institute.—This institute is famous both for the work of its illustrious head and for the excellent research work which it has turned out in recent years. There are on its staff such well known men as Kitashima, Shiga and Hata as well as a number of others whose researches are well known to specialists.

The Institute comprises the following departments:—

Scientific Investigations.

Clinical.
Post-graduate.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Biological preparations.
Testing of same.
Domestic animals.
Administration.

There is an experimental hospital of 57 beds which provides that scientific work will keep touch with the clinical aspect of disease; a necessity that is too often lost sight of.

There were a number of special investigations going on which we were able to see, though time did not allow of more than a somewhat cursory examination of details. The most interesting were as follows:—Tuberculosis, leprosy, rat-bite fever, hydrophobia (with the method used largely to immunise dogs), Weil's disease, distomiasis of the lungs and liver, Schistomiasis japonicum, Tsutsugamushi disease, dysentery (Shiga's work was done here), diphtheria, tetanus, and carcinoma.

Post-graduate courses are given twice a year to groups of 40 students, the courses lasting three months. 2,900 men have thus passed through Dr. Kitasato's hands since this work was begun.

The Government Institute for Infectious Diseases.—This institute is run on very similar lines to the last named, in fact this was originally Dr. Kitasato's laboratory until owing to a difference of opinion with Government he detached himself and started the institute which we have just reviewed.

This building suffered very badly from the recent earthquake and the main buildings were entirely destroyed and now the work is carried on in a series of 60 small buildings scattered about a spacious compound.

This again illustrates the interesting principle of subordinating a hospital to the need of a scientific institution for there is a six-ward hospital accommodating 100 patients and a full nursing staff and home for 50 nurses. There is also an out-patients department. There is accommodation only for 15 non-paying patients and the others pay from Rs. 10—Rs. 3 according to their means.

Non-paying patients are only admitted when the scientific interest of their condition justifies it and they have to submit their bodies to autopsy in case of death. The training school for nurses conducts a two years course before giving a certificate.

The institute publishes two journals, one of which is a prècis of experimental work done in Japan in English, German, French, and Esperanto.

A demonstration of researches was kindly arranged for us by Dr. Nagayo, the Director; it was of great interest and value to us especially those conversant with scientific research into disease.

The same spirit of enthusiasm prevailed here amongst the workers that we learned to expect in scientific institutions in Japan.

The Imperial Hygienic Laboratory.—This is devoted to work for public health authorities and more especially to the preparation, analysis and standardization of pharmaceutical preparations.

There are two main laboratories of this nature, one in Tokyo and the other in Osaka.

The staff (in Tokyo) consists of eight chemists and two physicians of whom one is a medical pharmacologist and the other a bacteriologist.

The hygiene department is concerned with analysis of water, milk, soil, food-stuffs, ices and mineral waters, whilst the pharmacological department is of wider scope.

It examines and standardises drugs used in the Pharmacopœia, and examines patent medicines for poisons and drugs of addiction, and safeguards the standards of their constituents.

Research is carried on into new and especially the indigenous drugs not recognised in the official pharmacopœia.

There is a large herbarium and extensive botanical gardens for controlling the growth of medicinal plants, which are run on modern lines.

The laboratory is self supporting by reason of fees charged and by the mass production and sale of registered medicines.

We saw some of the objects of reasearch such as—"Fugu," the ovaries of the Japanese goldfish.

Thymol carbonate, a tasteless and odourless substitute for thymol which breaks down into thymol and CO_2 in the intestine.

Large supplies of dried anterior and post-pituitary gland from the abbatoir.

Kawa-kawa, a narcotic and anæsthetic plant from the Hawaiian Islands.

The Field Laboratory at Amiya.—This was interesting as being the only field laboratory we saw and probably the only one there was. The problem of the transmission of intestinal diseases such as typhoid, dysentery, and helminthic infections is one of the most outstanding which Japan has to face.

There is no doubt that the incidence of these diseases is very high and shews no tendency to abatement but rather the opposite. There are several reasons for this, but the most important is probably the method of disposing of the night-soil which throughout the country is done by handing it over to the farmer and the market gardener for manurial purposes.

The work at this laboratory was designed to ascertain the length of time during which the fæces when kept under the ordinary conditions in domestic privies retained their infectivity, both bacillary and helminthic. There was also an attempt being made to devise a privy and cesspool which should sterilise the fæcal matter before it is handed over to the farmer.

The persistence of typhoid infection in stored fæces is much longer than we are accustomed to consider probable in the tropics.

With an average temperature of 15.9°C. typhoid bacilli remained living for 47 days; at 18.8°C. for 44 days; and at 18.2°C. for 39 days. With higher temperatures such as around 25°C. the persistence was much lower, viz., 4 to 10 days and sometimes less. This suggests that in India with its higher temperatures bacilli of enteric and dysentery groups would not persist longer than 3 or 4 days.

With the ova of worms the duration of life was still longer, viz., hookworm eggs persisted for 86 days at 18.7°C.; for 84 days at 22°C.; for 66 days at 22.5°C.; and also at 23.7°C.; and about 40 days at 25°C. The eggs of roundworms persisted even longer, 99 days at 18.7°; 97-66 at 21.9°C.; and 63 days at 23.7°C.

The idea of the investigators was to allow decomposition to go on in the pits till the bacteria and ova were destroyed and then to issue the fæces to the farmers and for this purpose a special type of cesspool was under investigation.

The final results of this investigation will be of interest in all tropical countries.

The Imperial Government Institute for Nutrition at Tokyo.—This laboratory impressed me and my colleagues on the League of Nations Interchange as the most notable of all the institutions which we visited in Japan. We agreed that we would impress upon our respective Governments the desirability of doing something of a like nature in other countries in the East.

The Japanese have always been in the forefront where defects of nutrition and deficiency diseases required investigation, and the abolition of beriberi in the Japanese navy was a world-famed example of this. The names of Takagi, Mori, Suzuki, and Kumagawa are well known in this connection and their mantle has fallen on the shoulders of the present director and founder of this new school of nutrition.

Dr. Saiki is a man of great personality and abounding enthusiasm and we paid repeated visits to his institute to familiarise ourselves with the principles on which it is conducted.

His full report is unfortunately printed in Japanese but he is engaged in translating into English and this edition will be awaited with great interest. He experienced some difficulty in financing the English edition, so the Director of the Health Department of the League of

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Nations, Dr. Rajchman, who was with us in Tokyo agreed to obtain from the League a grant to enable Dr. Saiki to hasten the new edition.

Dr. Saiki has working with him six medical men, five pharmacologists, six agriculturalists, four chemical engineers and some others.

His budget is Yen 150,000, i.e., about 2½ lakhs of rupees.

The institution is divided up into four departments, viz.:—

(*a*) Investigation of the fundamental science of nutrition.

(*b*) Investigation of the applied science of nutrition.

(*c*) Department of enquiry, statistics, exhibition and propaganda.

(*d*) Department of administration.

(*a*) The first named is sub-divided into the following sections:—

1. Food chemistry.
2. Metabolism.
3. Physiology and pathology.
4. Microbiology.
5. Physics.

(*b*) The department of applied nutrition is divided into:—

1. Investigation of food materials.
2. Natural food products (including aquatic products and famine relief food products).
3. Food industries.
4. Investigation of the animal and plant kingdom for new foods.
5. The division of economic nutrition.
6. The division of preservation and distribution of food-stuffs.
7. The division of cookery and table ware.
8. The division of infantile nutrition.
9. The division of utilization of waste products.

We saw much work of great interest on these various problems. One or two remain particularly in my mind such as—

Beautifully hand coloured drawings of the various foods which might be used as substitutes for the more usual in times of shortage. Dr. Saiki had tried these all on himself and devised methods of cooking to make them palatable, much as our Frank Buckland is said to have eaten pieces of the flesh of all the creatures which died in the London Zoo.

The methods of producing and dissolving stones in the bladder and kidneys of animals by changes in diet with special reference to vitamines (a subject of great possibilities to India).

The production of cancerous changes in the stomachs of rats by vitamine defects.

Cheap and nutritious menus prepared for poor families and published in the daily press.

Pamphlets and hints on cooking published in the press and broadcast in pamphlet form.

Lectures to school teachers and educationalists on the principles of nutrition.

Studies in animals on the relation of diet to reproduction.

Propaganda posters and a very good exhibition where all the common food-stuffs were shewn in models with comparative figures as to their relative nutritive values.

These are some out of the many valuable things which Dr. Saiki had to shew us. He also shewed us an interesting method of distinguishing the age of rice and its probable content of vitamine B.

Chemical Method of distinguishing the age of rice.

Take polished or unpolished rice of unknown age. Make a solution of—

Paraphenylendiamin, 1 per cent. ..	5 c.c.
Watery solution of gulacol, 1 per cent.	10 c.c.
Hydrogen peroxide, 1 per cent. ..	0.2 c.c.

Pour this solution over the rice in a Petri dish.

When the rice is new it turns purple in under 3 minutes.

When the rice is old there is no change in colour.

Saiki says the reaction is due to an enzyme or catalyst which is either vitamine B or runs parallel with vitamine B.

This test determines—

The age of the rice,
The degree of polishing,
The presence of vitamine B.

I wish to impress upon those who read this report the necessity there is that India should take up more fully this important study of nutrition and I intend to return to the subject at a later date.

MEDICAL EDUCATION IN JAPAN.

A student who intends to take up the study of medicine would ordinarily enter a middle school at the age of 12 and work there till 17.

He would then compete for a place in one of the Higher Schools and if successful would complete three years in this school in learning such pre-science and pre-medical studies as mathematics, zoology, botany, physics and languages such as Chinese and either English or German, one of which latter two is compulsory. Most advanced men take both these languages but until recently most of the science and medical students took German. Since the war however and especially due to the fact that most post-graduates go to America rather than to Germany, English is the prevailing language.

Emerging from these Higher Schools the student proceeds to one of the Universities or higer medical schools and undergoes four years of study in purely medical subjects.

There appeared to be another portal comparable to our "Double College" examinations at home, and this would be chosen by those who had not succeeded in getting into one of the pre-medical schools and who would have a somewhat lower standard of general education. For the higher schools and the university courses there are generally more applicants than vacancies so that these examinations are actually competitive.

There are five Imperial Universities, five Government Medical Colleges, four public Medical Colleges, and two private Medical Schools.

There are also four private higher medical schools which are outside the Universities ordinance.

These higher medical schools both public and private are to be abolished and the universities extended to meet the growing needs of the community.

We visited several of the Imperial Universities, one or two of the Government medical colleges, and the Private Medical College of the Keiogijuku University.

Speaking generally there appeared adequate accommodation and equipment in the laboratories and class rooms of these institutions, but the Imperial University at Tokyo shews sad evidence of the ravages of earthquake and fire which had caused overcrowding and deficiencies in equipment which were inevitable. The great library of 700,000 books was completely destroyed in a few hours, a loss great as it was, being merely an incident in so great a holocaust.

It is almost impossible for an outsider especially on such a cursory examination as we were afforded to form any real estimate of the standard of medical education which these universities and colleges afford. The men with whom we came into contact were naturally the pick of their profession and we had little opportunity of judging the level of the average medical practitioner which is the ultimate standard of medical education in the country.

I should expect however that the average general practitioner was definitely on a lower plane than his colleague in the most civilised countries in Europe.

There are no special schools in hygiene and no diploma in public health. Hygiene is amongst a large number of other subjects for the final examination but it takes a very small place and we were informed that very few men can be found to take up work in public health so that in this respect the medical service of Japan is markedly behind hand. This was reflected in many ways because although on paper the public health

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

organisation was excellent, in actual practice it was sometimes obviously defective.

The "Yoshiwara" system is in vogue, that is, a separate part of each city retained or set apart for prostitutes.

In the year 1927 there was a daily average of 48,000 prostitutes in these licensed quarters and the total number of medical examinations of these in the year was 3,068,180 of which 71,575 revealed venereal disease. The amount of venereal disease per head of prostitute per year was only 2.33 per cent. Each woman was admitted to a lock hospital 1.48 times per year for an average duration of 18 days. The medical examination of prostitutes is carried out frequently and any diseased are forced to go into a lock hospital till cured. It is stated that geisha (dancing girls) and waitresses and other young women especially exposed to risks have by law to submit to periodic medical inspection. We visited the lock hospital in Tokyo but the inspection was not satisfactory as the patients were kept out of the way and the figures shewn to us were incomprehensible. The building and furnishing was much below the usual standard of Japanese hospitals. We were not given an opportunity to inspect the medical arrangements provided in the Yoshiwara but understand that anti-venereal methods are taught to the girls. The amount of disease amongst the general population is difficult to arrive at, but judging from the amount amongst the women one would suppose the percentage to be high. The figures giving the infections amongst recruits coming for army examination is only 15 per cent. and has been steadily falling. There are no figures to shew the percentage of a positive Wassermann reaction in a random sample of the population. We asked a number of questions on this subject at the final conference and it struck me there was a good deal of official reticence in the matter, but it seems that the system they have given rise to less offence than the more open methods seen in Europe. At any rate street solicitation is entirely absent in Japan, at least it seems so to the foreign eye. It appears that anti-venereal measures are entirely directed towards the female sex and that there is no arrangement made for male prophylaxis or treatment, other than the out-patient departments of the ordinary hospitals and by private physicians.

Miscellaneous Public Works.

The Water Works at Tokyo are very large and kept in excellent order. The water comes from the River Tama many miles away and is led into two large reservoirs, which we visited, about ten miles outside the city, the capacities of which are 138 and 510 million cubic feet respectively. It is then brought into Tokyo and passed into settling ponds, four of them, each holding 3 million gallons. It then passes into filter beds 9 ft. thick, i.e., 3 ft. sand and 6 ft. of gravel.

It passes through at 5 inches an hour or 10 ft. in 24 hours, the sand is cleaned once a month and three inches of bacteria and algæ removed. There are 24 filter beds each about 7,000 sq. feet.

About 60 per cent. of the inhabitants of the city use the piped supply, the rest use well water. This system supplies 11 to 12 million gallons per diem but this is insufficient for nearly 2 million people so there is a big extension on foot. This when complete will supply 18 million gallons per day which will allow 6 gallons per head per day for a population of 3 million people. The present population of the city is said to be 2,180,000 but we understand that since the earthquake it has fallen to below 2 million and now takes second place to Osaka.

The cost with the proposed extension will amount to about 57 million yen, i.e., about £5½ million sterling.

The average bacterial counts per c.c. are:—

At the source 1,940 colonies
Settling pond 1,953 colonies
Filter bed 11 colonies
City hydrant 29 colonies.

(presence of *B.coli* not given.)

Sewage Disposal.—This is a matter in which Japan is very behind hand, for with a few exceptions there is no water-carriage system of sewage disposal in the whole country. Even in the largest cities, the privy or midden system holds. The Japanese are dependent largely on the farmer and the market gardener for much of their food and it has always been the fixed custom to use the valuable manurial qualities of human excrement for the fields and gardens. Until recent years this had a definite market value and it was the custom for the farmer to send in to the towns and cities to buy, and collect free, from the householders their privy contents. More recently the amount of agriculture near the cities has been reduced and wages have gone up so that farmers will no longer trouble to collect the manure even on payment. The municipalities have had to take over this duty in the cities and either deliver it for sale direct to the farmers or dump it in the river or in the open country.

In Tokyo, a commencement has been made in the sewerage system and a disposal plant started which we saw. As however, there is practically no water carriage system in vogue the nuisance is very little abated. The sewers have hoppers opening on to the street in certain places and down these are shot the fæcal matter collected from neighbouring cesspools. The sewers are chiefly useful to conduct storm water sullage water from gullies and nallahs and such trade effluents as are discharged into them. The greater bulk of the cesspool contents are still carried through the open streets in tubs on an ox-cart and it is not uncommon to meet a score of these unsavoury vehicles and perhaps to be jammed in traffic behind them. The contents are liable to slop over and swarms of flies are attracted to the tubs and to the spillings.

This being the state of affairs one does not wonder that the chief cause of death in Japan is "diarrhœa and enteritis" which easily heads the list with nearly 120 deaths per thousand. This does not include typhoid fever or dysentery which add 10 and 2.8 respectively.

The infant mortality is too high for the temperate zone and has slowly risen from 145 in 1913 to 157 in 1922 per 1,000 infants under one year. It seems indeed that the high death-rate due to these diseases is due to the high infant mortality due to the same cause, as in the age distribution of "diarrhœa and enteritis" out of 1,000 deaths at all ages no less than 702 are in infants under one year.

Disposal of Refuse.—This system is as little developed as is the sewage system.

Only 8 cities and 3 towns have any facilities for incinerating rubbish, 5 other cities and 8 towns burn it in open dumps and the rest dump it unburnt or use it for "making" land.

We saw 2 incinerators, one in Osaka which is the most up-to-date in Japan and one in Kyoto.

There is nothing much to describe about these as they are of the usual pattern except that concrete blocks and drain pipes are not made from the final products of incineration as they are in England but the ashes are sold as having some manurial value.

Only about a third of the city garbage is thus disposed of: the remainder is either sold in its original state as fertiliser or is dumped into lakes or lagoons.

Primary Schools and School Hygiene.—One of the most praiseworthy aspects of national life in Japan is the extraordinary amount of attention both State and private which is accorded to children and young people.

The shrine and palaces and national monuments are thronged with parties of children and young people such as boy-scouts and girl-guides being led round and taught concerning the national treasures, its sacred places and its memories of national heroes and great men.

The result is an intense national pride and patriotism which is one of the most remarkable features of the people. Every opportunity is taken to educate the young and I remember on a cold morning in the Inland Sea at 6-30 a.m. seeing the captain of the ship

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

holding a class for young people on the principles of navigation.

This explains the unity of the nation, their desire to acquire knowledge, their obedience to discipline and their reverence for the Emperor and his officers right down to the lower grades of official. The national religion of Shintoism, i.e., ancestor worship, contributes to this feeling of passionate nationalism.

We only visited one school, the Bancho Primary School, but were full of admiration of the organisation, the equipment and the attitude of the children. On looking through the duties and the regulations defined for their daily life one only wonders that they have any time to be just children and the règime would seem to be over organised and destructive of individualism, at any rate to the English mind. The normal children have every attention but the abnormal, the mutes, the backward and those defective physically have if anything still more care.

Physical Culture.—We were taken to watch the national games at the Meiji Shrine and on other occasions saw displays of judo, jujitsu and fencing.

These martial exercises are universally indulged in by the youth of both sexes and have a more obviously serious import than the games of our young people. In the words of the prospectus of Butokkwai "the object of these exercises is not only to teach the art of self-defence but also to cultivate the spirit of knightly valour. This spirit is a crystallization or combination of the personal virtues, courage, kindness and fair dealing."

The Institute of the Science of Labour.—This new science has already some recognition in Japan and we were able to pay a very rapid visit to the institution and to see something of its work.

Work was in progress on such problems as the following:—

Studies in industrial fatigue.
Studies of the factors affecting growth.
Studies of the factors affecting mental development.
Studies of the factors affecting physiological functions.
Industrial development and the birth-rate.
The evils of night work in factories.
Temperature, humidity and ventilation in workrooms. (In this work Leonard Hill's katathermometer was in use.)
Individual disposition and efficiency.
Physiological selection of workers.

The laboratories were well supplied with the most recent instruments for psychological research.

It is interesting to note that this institute was started by a big mill-owner and the work tested on his own operatives.

A very interesting paper on this subject was read at the recent congress in Tokyo by the Director of this institute entitled "Woman in Industry and her Sanitary conditions."

His conclusion is that "women are working under extremely unsuitable conditions. These inhuman labour conditions and the deficient factory administrations have found expression in the high rate of absence from work and the frequent rate of sickness."

Welfare of Railway Employees.—These Government servants have a special organisation to safeguard their interests.

Abattoirs.—These which were formerly in private hands are gradually being taken over by municipalities so that there are 328 public and 329 private ones. We saw the ones in Tokyo and Osaka.

The method of killing is very humane. A heavy metal hammer is placed against the forehead and a cartridge exploded into the brain which drops the animal immediately. It is then pithed with a bamboo wand. The surroundings were quite sanitary and there are full inspections of the live animals and of their flesh after death. Tuberculosis is almost unknown in cattle, Professor Nagoya could only remember about five cases in 20 years' experience.

It is evident that bovine tubercle cannot be a cause of the very high incidence of the human disease in Japan.

We were very interested to see in all the abattoirs a stone pillar erected in the entrance with an inscription on it and to learn that the butchers bowed to this on entering for their day's work.

We were told that this is a memorial to the memory of the cattle which are slaughtered and a free translation on the stone would be "To the spirits of the honourable animals who die here."

There are similar shrines in some laboratory gardens to the spirits of the animals used for experiments and Prof. Shiga informed us that there is a certain day set apart when offerings of rice and other things are made at these shrines.

This practice is of Buddhistic origin.

Crematoria.—The large majority of the dead bodies are cremated, at least in the cities. In Tokyo for instance about 90 per cent. of all dead are cremated and only ten per cent. are buried either in cemeteries or more rarely in the gardens of temples. Crematoria are privately owned and the one we saw in Tokyo was a very up-to-date electric apparatus.

Milk supplies.—Milk is not a favourite article of diet in Japan and it is only recently that its sale has increased sufficiently to require Government supervision. Children are fed on pap and rice in default of their mother's milk and of recent years the importation of dried and condensed milks has been going up very rapidly.

Vaccination.—The population is very well vaccinated as the ratio of unvaccinated per 1,000 were:—Below one year 14, below 2 years 6.8, below 3 years 4.1, below 4 years 3.1 and below from 4 to 15 years 7.7, figures which compare favourably with any country in the world. The vaccine lymph is sterilised by the chloroform method and appears to maintain its potency for three months, except in the hottest season.

CONCLUDING REMARKS.

This Japanese tour has been of great value to me as a personal experience, but one of its objects, perhaps its chief one, was that India should benefit by the comparison of her institutions with those of another Asiatic nation.

It must be realised from the first that there are several reasons why that comparison is very difficult.

In comparing two places from the point of view of public health the matter of prime importance is the relative geographical position of the two, which is the factor governing their respective climates and consequently their indigenous diseases and the chances of any epidemic diseases which reach them of establishing epidemic conditions.

The second is what we may call the "basic sanitary unit" which is the individual of which the nations are composed.

In both these respects Japan and India differ fundamentally.

Japan though an Eastern nation is under conditions to be found elsewhere in the temperate zone, and her conditions though comparable to Europe and the United States were not so with other eastern nations which are in the tropics and sub-tropics, and it was from these countries that almost all the delegates to the inter-change had been deputed.

The factors governing the "basic sanitary unit" were almost as different.

The Japanese are essentially a clean race, clean in their persons and meticulously clean and tidy in their habitations and their surroundings, they are a united nation with one creed, without religious prejudices and without caste, they are of a high standard of general education, quick to see the reasons for a desirable change and willing to accept it, obedient to authority and withal of a passionate and almost fanatical patriotism.

With a people so plastic and so malleable it is easy to see that the path of a reformer is an easy one.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

The Japanese people have been undergoing since these last fifty years or less a veritable renaissance, and public health has undergone and is still undergoing remarkable progress.

I am well aware that they shewed us what they wished us to see and equally aware that they had skeletons in their sanitary cupboards, but the point is that they knew they were skeletons and were in every case planning to get rid of them. There was nothing we could suggest that they had not already considered and in most cases had schemes to improve undesirable conditions even if those schemes were as yet scarcely beyond the paper stage. I read carefully a pamphlet styled "Health Organisation in Japan" which was prepared especially for the League of Nations and for our visit, and after reading it I wondered what there could be left to criticise or to suggest, but our first drive through the streets of Tokyo convinced us that to a considerable extent theory had outrun practice.

The condition of the streets, the crude way of filth disposal were quickly borne in on us, but later we realised that the former could in great measure be explained by the late disastrous earthquake and for the latter their best endeavours were being made to find a solution.

The students take very kindly to medicine and especially to research; they are clever with their hands and prefer practical work to theory and book reading.

As a result the hospitals and laboratories and other medical institutions are crowded with keen and energetic students and doctors and both they and the nursing and the technical assistant class are available in very much larger numbers than in similar Indian institutions.

As to the financial side, I am not able to make a comparison, but I judge that very much larger sums are voted for medical budgets in Japan than in India according to any standard that one may take.

The result is that the scientific institutions and the hospital wards and particularly the out-patient departments are extremely well, even lavishly, equipped with all the latest instruments of precision.

Apart from these matters the institutions I should most like to see transplanted to, or copied in, India are their port quarantine arrangements, their leper asylums their mental hospitals, and certain scientific institutions —particularly their Institute of Nutrition. I speak here without knowing very much personally about the first named, but for the others I know the Japanese models would be a decided advance on anything we have in India.

If I had one recommendation to make it would be in favour of the Institute of Nutrition, which struck us all as the most vivid of all the institutes we saw in Japan. I went so far as to ask Dr. Saiki supposing he were approached, would he be willing to come to India and advise the Government of India on the question of starting a similar Institute for India.

I think that if the laboratories were built and equipped it would require a budget of not less than two lakhs per annum, but I think that first of all Dr. Saiki should be asked to come and give his views.

It would not be proper to close even an official report without some reference to the almost overwhelming and lavish hospitality shewn to us by our Japanese colleagues, to their courteous reception of our party and of our numerous enquiries at every turn.

We were given freely of all information we required and their organisation of the complicated tour of eighteen foreigners, speaking more than one language, visiting in parties of six a very large number of different places in sequence, must be realised in order to be fully appreciated.

At the same time if such an inter-change is to take place in India, there are ways in which the procedure should be modified and even improved, but the organisation will not be improved upon and India will certainly not be able, as I warned them, to reach such a scale of hospitality and of public recognition as was shewn to us.

This report is written in Peking and here also I have been able by the kindness of the Chinese Government to get some insight into their public health system and it may be some consolation to India to know that she is as far ahead of China in matters of public health as Japan is ahead of India.

Current Topics.

The Ronald Ross Gate of Commemoration.

AN exceedingly interesting ceremony took place in Calcutta on Friday, January 7th, 1927, when His Excellency Lord Lytton, Governor of Bengal, unveiled a commemorative gate in honour of Sir Ronald Ross near his old laboratory in the Presidency General Hospital. The memorial is in the form of a gateway bearing a bronze medallion of Sir Ronald in the centre above the arch; whilst on the left is an inscription to the effect that in the small laboratory 70 yards to the South-East of the gateway Sir Ronald Ross made his ever-memorable discovery of the mosquito transmission of malaria, and to the right of the medallion is a quotation from a poem which he wrote when he first found that the malarial parasite underwent development in a mosquito. We give below a photograph of the memorial; also a photograph of the medallion, for which Sir Ronald gave special sittings in London last year. There was a large gathering of the leading citizens of Calcutta.

In asking His Excellency to unveil the memorial, Lieut. Colonel J. W. D. Megaw, C.I.E., V.H.S., I.M.S., spoke as follows:—

Your Excellencies, ladies and gentlemen,

It is astonishing that so few of the inhabitants of Calcutta know of the existence of the little laboratory a few yards from this spot in which Sir Ronald Ross made one of the greatest discoveries in the history of the world. In the hot weather months of 1898 Surgeon Major Ronald Ross, I.M.S., found out how malaria is conveyed by the mosquito.

This discovery has been exploited to some extent; it has led to the saving of many thousands of lives, and to the reclamation of large tracts of country which would otherwise have been uninhabitable, but though 28 years have elapsed since it was made, we are only beginning to scratch the surface of the vast mine of wealth which it has placed in our possession.

If Sir Ronald's discovery were fully applied it would add millions of healthy human beings to the population of the earth, it would bring health and prosperity to many millions who now exist in poverty and ill-health. There is no other discovery for which such claims can justly be made.

About ten years before he made his great discovery Ross wrote the following lines which breathe a prophecy and a prayer:—

"In this, O Nature, yield I pray, to me.
I pace and pace, and think and think, and take
The fevered hands and note down all I see,
That some dim distant light may haply break.
The painful faces ask—'Can we not cure'?
We answer 'No, not yet; we seek the laws.'
O God! reveal through all this thing obscure
The unseen, small, but million murdering cause."

The answer to the prayer came after years of toil, but even before he had completed his discovery his confidence of victory was expressed in the lines which are now inscribed on the gate of commemoration which Your Excellency is about to unveil.

"This day relenting God
Hath placed within my hand
A wondrous thing, and God
Be praised, at His command,
Seeking His secret deeds
With tears and toiling breath
I find thy cunning seeds,
O million-murdering Death!
I know this little thing

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A myriad men will save.
O death! where is thy sting,
Thy victory, O Grave?"

"A prophet is not without honour save in his own country." Sir Ronald's offence did not consist merely in being a prophet, he added to it by being a poet and a scientist, and so he trebly earned the indifference with which his great work was received in India.

Sir Ronald, not unnaturally, has often complained of the apathy and even opposition which he encountered. I have sometimes thought that the obstacles which were placed in his path may have been blessings in disguise. There are a few men of genius like Sir Ronald Ross and Sir Leonard Rogers, to whom obstacles are but stepping stones by which they climb to still greater heights of achievement.

If Sir Ronald had lived in times like the present under the benevolent rule of Your Excellency, he would have had no cause to complain of lack of encouragement or recognition; but would he have accomplished so much if he had been the pampered protégè instead of the grim and misunderstood worker, who had to fight for every opportunity to carry on his research? Certainly he could hardly have done more. He not only discovered how malaria is conveyed, he showed how the disease can be controlled. He himself at first was the only one who had the clearness of vision to see the vast results which would follow from his work. He was sadly mistaken

The Ronald Ross Gate of Commemoration.

when he imagined that the world would at once perceive the value of the great gift which he had placed at its disposal. The men of science might have been expected to realise the great possibilities of his discovery, but even they were unable to make the forward intellectual stride which was needed if they were to form a true estimate of its value.

Ross was years ahead of his times: in those days the suggestion that disease could be controlled by suppressing mosquitoes provoked a sarcastic smile and the author of the proposal was regarded as an enthusiastic visionary. This indeed he was, but not in the vulgar sense, his vision was clear and his enthusiasm justified. It was the people of the time whose eyes had not yet been opened.

The completeness of his discovery was remarkable. If we knew nothing about malaria except what Ross found out, we should still be able to control the disease. If our knowledge consisted of what others discovered independently of the work of Ross we should know but little of the means of preventing malaria.

It is, therefore, not surprising that we should be so eager to mark the birth-place of his discovery. What is surprising is that after so many years it should be left to us to have the privilege of doing so.

The gate of commemoration which Your Excellency is about to unveil, though small in size and insignificant in appearance, will form a land-mark in the history of civilisation.

In unveiling the Memorial, His Excellency Lord Lytton made the following speech:—

"Ladies and gentlemen,

Colonel Megaw is quite right in saying that the ceremony which you have asked me to perform to-day is one that gives me unusual pleasure. We are commemorating an event from which every class in the community has already derived benefit and may yet derive even greater benefits in the years to come. We are honouring a man whom every Englishman and every Indian without distinction of creed or party is glad to honour. Seldom indeed has it fallen to my lot in the last 5 years to find myself the spokesman of such a completely unanimous opinion. There is not a man or woman in the whole of India who would grudge Sir Ronald Ross the highest measure of praise and gratitude which can be expressed in words.

His achievement, I think, is even greater than Colonel Megaw has described it, and I don't think any one will accuse me of exaggeration, if I say that Sir Ronald Ross's discovery has been the greatest contribution to medical knowledge since the days of Pasteur. So familiar are we now with the connection between malaria and the mosquito that it is difficult for us to realise how startling was the first announcement of this fact, nor how sceptical was the generation to which it was first made. Yet this knowledge, on which so much depends, we owe not to any accident but entirely to the patient, thorough and successful research of one man—the man whom we have met to honour.

The consequences of this discovery which seems to us so simple, so obvious, have had, as Colonel Megaw has reminded us, the most far-reaching results. Not only has it revealed the cause of malaria, improved the treatment of the disease, helped towards its prevention and indicated the steps by which it may one day be eradicated, but it has also led to research along similar lines into the causes and treatment of other malignant epidemic diseases. Indeed, the whole of that magnificent and valuable institution of research of which Colonel Megaw is now himself the distinguished Principal may be truly said to owe its very existence to the work of Sir Ronald Ross.

Reading through the *Memoirs* of Sir Ronald's life, one is struck by his versatility, his high idealism and his perseverance in the face of difficulties and obstruction; and it is such qualities as these that have made him one of the world's greatest benefactors. There is also another side of his personality which deserves to be mentioned. I was once told that the historian Lecky, whose friends would never have suspected him of harbouring military ambitions, once confessed to a friend that the great regret of his life was that his parents had not made him a soldier, and he has left on record a poem in which this strange regret is half revealed:

'Not every thought can find its words,
Not all within is known;
For minds and hearts have many chords
That never yield their tone.
Tastes, instincts, feelings, passions, powers,
Sleep there unfelt, unseen;
And other lives lie hid in ours
The lives that might have been.'

I half suspect from the lines which Colonel Megaw has quoted, and some of which are reproduced upon the Gate of Commemoration which I shall presently unveil, that Sir Ronald Ross too is conscious of a 'life that might have been' and would perhaps rather be honoured as a poet than as a man of science. If so, this only reveals to us the breadth of his human sympathy, and adds to the measure of our appreciation of him. His self-imposed mission was to rid India of the scourge of fever from which it suffered, and he worked incessantly, ungrudgingly, in spite of disappointment and difficulties which might well have deterred other men from their purpose, until after four years of unremitting toil he succeeded in finding the secret. Not content with disclosing the secret for the benefit of mankind, he completed his task by laying down detailed plans for the control of the disease.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Four years after he made his discovery Sir Ronald Ross had an opportunity of making his first great demonstration of its vast possibilities by freeing Ismailia of malaria at a time when the evacuation of the town was being seriously contemplated. He therefore showed by their practical application the immense value of the principles which he had established. So comprehensive were the plans he laid down that it was on their basis that all the great successful experiments in freeing the Panama Canal zone and other areas were subsequently carried out. It is nothing short of miraculous that such results should have been obtained by the discovery of one man and that he, almost unaided, should have been able to detect not only the means by which malaria is carried, but also the means by which it can be prevented.

Another fact which we are commemorating to-day and which we in Calcutta are proud to remember is the fact that this momentous discovery was made in this city in a small laboratory a few yards from this spot. That nearly 30 years should have passed without any recognition by Calcutta of Sir Ronald Ross's services to humanity is a reproach to this city, which I am glad to say is now at last going to be removed. It is customary to erect monuments and commemorative tablets to mark the sites where men have died or are buried, but so far as I know there are few such monuments to mark the place where knowledge has been born. Yet what could be a happier subject for commemoration than the birth-place of knowledge? We are all proud that Calcutta should have this distinction, but unfortunately other parts of the world have as yet derived more benefit from Sir Ronald Ross's discovery than the Province which gave it birth. Panama, Ismailia and West Africa owe their freedom from fever to his work. The Malay Peninsula, he tells me, is making good use of it. Bengal in 30 years has profited but little by it and is still a victim to the ravages of this disease. That is another reproach which after to-day's ceremony I hope we shall do something to remove.

There are two agencies in this Province that are concentrating the best available experience upon a war against disease. They are the School of Tropical Medicine and the Co-operative Anti-Malarial Societies—the one an official and the other unofficial organisations. The best memorial we could erect to Sir Ronald Ross, the best use we could make of his discovery for the benefit of Bengal would be to raise a large endowment fund for the support of these two organisations. The School of Tropical Medicine is carrying on Sir Ronald Ross's work, is adding every year to our knowledge of the causes of diseases and the methods necessary for their prevention. They are the Intelligence Department of the Army of Health. The Co-operative Health Societies are the field force, they are carrying the knowledge obtained by the School of Tropical Medicine into the homes of the people and enlisting their co-operation in preventive measures. Funds are urgently needed for the support of each and I hope that as a result of this meeting a movement will be set on foot to raise a fund associated with Sir Ronald Ross's name to develop the work which these organisations are doing, and to carry it into every village in Bengal.

Sir Ronald's discovery has been worth many millions of pounds to the human race, apart altogether from the saving of life and the prevention of sickness. By the application of the principles which he laid down we can save many more lives and money for Bengal, we can restore the vitality of the Province and enable her to take a more prominent and valuable place in the work of the Empire."

Sir Ronald Ross, who was obviously deeply moved with emotion, then made a brief speech which was in his happiest vein. He spoke as follows:—

"Your Excellency, ladies and gentlemen,

I trust that you will excuse me if my remarks are but brief. There are some moments in a man's lifetime when he is so overcome with emotion that he can hardly speak, and this is such a moment to me. I can only say that it is the proudest moment of my life. It is but rarely that men of science receive such recognition during their lifetime. I feel that I ought to be dead; but there is a good deal of life in me still.

If I may, Sir, I would like to recall the names of a few of the many who were associated with me in research work in malaria. I would refer to Dr. Alphonse Laveran, my master, who discovered the parasite of malaria, a man whose genius was typical of the great nation from which he sprang. I would refer to Sir Patrick Manson, from first to last my sponsor, and the man who put me on to the right trail. I would refer to Surgeon-General Harvey, at that time Director-General, Indian Medical Service. It is true that during these years of work I complained constantly and continuously. But what is the use of being a great man if one is not allowed to 'grouse'? My grievances were genuine. It is true that my work was subject to constant interruptions. Surgeon-General Harvey could not help that, he could not prevent it, but he did his utmost to mitigate the circumstances, at every step he showed his interest and did all that he could to further my work. I would also like to refer to the subsequent work of many workers in India, including such men as Christophers, James, and Bentley.

Medallion on the gateway.

Discovery is always progressive and I should like to refer to the many workers who have added to our knowledge of malaria, many of them worked in India, their names are well known. I should like to mention a little incident that happened while I was working in my little laboratory. The late Colonel Maynard always took a keen interest in my work. I well remember the morning when I first came across the oöcysts of the parasite of bird malaria in mosquitoes. I rushed out of the laboratory and came across him about a hundred yards from the hospital. I said to him 'I have got them again.' He looked greatly astonished and evidently suspected me of having got something quite different from oöcysts, but when he came to the conclusion that I was still in my sober senses—though he was probably sceptical as to the importance of the insignificant little objects which I showed him—he came across to see them.

I would like to refer to my bearer, Lachman. He is here to-day, standing in the corner of the tent. He was a faithful and a valuable servant and one who did much to help me in the laboratory. I would like to refer to my laboratory assistant, Mahomed Bux. He is dead now, poor fellow; he was for many years in the laboratory here after I left and he died here. He had

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

only one failing, a fondness for smoking Indian hemp. At nights after he had had his pipe, his last conscious action before he fell down stuporous would be to chase away marauding cats from the mosquito nets within which were my birds and my mosquitoes.

Revisiting the scene of my work, Sir, after a lapse of twenty-eight years, I see very great changes. My old laboratory used to have black, soot-stained walls. It is now red. The hospital used to seem much closer to the laboratory than it now is. There was a simply magnificent ditch just outside the laboratory. I had only to step out of the laboratory and dip a pail into it to obtain a rich supply of various kinds of mosquito larvæ. They have gone and filled in that ditch. The place seems changed, somehow, and I much regret the disappearance of my valuable old ditch.

In conclusion, Your Excellency, I can only repeat that I am very conscious of the great honour which you and the citizens of Calcutta city have done me by erecting this memorial to my work."

After Sir Ronald's speech, His Excellency left the *shamiana* erected for the ceremony, crossed the road,

Sir Ronald Ross, K.C.B., K.C.M.G., F.R.S., standing at the gate.

and unveiled the memorial. He then opened the commemorative gateway and was conducted by Sir Ronald to the laboratory in which the great discovery was made.

The commemorative gateway faces on Lower Circular Road in front of the Presidency General Hospital, Calcutta; and it will be in full view of the thousands who pass along that road daily.

On Monday, the 10th of January, Sir Ronald delivered a lecture on malaria to a large audience at the Empire Theatre, Calcutta, under the presidency of His Excellency the Governor of Bengal. Sir Ronald told the story of his discovery to a deeply interested gathering. He referred to the recently established Ross Institute in London and thanked the many subscribers from India who had helped in promoting the cause of the Institute.

When not to Operate for Hernia.

(*British Med. Journ.*, Sept. 11, 1926, p. 486.)

MR. MCADAM ECCLES holds that there are a number of conditions in connexion with hernia which negative operation. In the following cases operation is undesirable:—

1. *The very young.* Because: (*a*) Nature tends to bring about a cure. (*b*) Very young children do not stand operation well. (*c*) Asepsis is uncertain.

2. *The "aged"* (over 60). Because: (*a*) The tissues are not in most cases such as allow of a radical cure. (*b*) Persons do not like operation and then to have to wear a truss. (*c*) A properly made and properly adjusted truss will bring about such an improvement that the person may not know that he has a hernia.

In Males.—(*i*) In large inguinal hernia it is difficult to occlude the inguinal canal and the apertures sufficiently, so long as a passage for the spermatic cord has to remain. (*ii*) Where there is much disturbance of micturition, the result of enlargement of the prostate.

In Females.—(*i*) Cases in which pregnancy is present in the later months; (*ii*) where the abdominal wall tissues are weak, particularly as the result of stretching from repeated pregnancies.

In Cases of Visceral Lesion.

Heart.—Advanced cardiac disease negatives an operation. Operation may have to be undertaken for strangulation as a last resort.

Lungs.—Any advanced pulmonary lesion. (*i*) A general anæsthetic is contraindicated, although a local one might be used. (*ii*) Cough produces a liability for the return of the hernia.

Kidneys.—Any advanced disease of the kidneys.

Liver.—Especially when ascites is present.

Some General Conditions.

Obesity.—Unless reduction of the fat can be brought about.

Ptosis of the abdominal organs in any marked degree.

Dermatitis, until this is cured by proper treatment.

CERTAIN TYPES OF HERNIA ARE UNSUITABLE.

1. *Inguinal Hernia.*—A largish inguinal hernia with feeble abdominal walls, and with much dilatation of inguinal apertures, is very unlikely to be "cured" by operation. It may be controlled by proper truss pressure, and by this the danger and discomfort of the hernia will diminish most appreciably. An operation then may place the patient in complete safety, and enable a light efficient truss to be worn with comfort so as to prevent recurrence.

An inguinal hernia which has recurred is very unlikely to be cured by operation, and a suitable truss is then advisable.

2. *Femoral Hernia.*—A femoral hernia of a large size is more difficult of cure than an inguinal. It is well again to try to obtain control of it by a truss, and subsequently to consider operation, with a view, not perhaps of cure, but of rendering the wearing of a proper truss efficient and safe.

A femoral hernia which has recurred is still more unlikely to be cured by operation, and a suitable truss is then advisable.

3. *Umbilical Hernia.*—(*a*) Infantile acquired: There is a great tendency for these small umbilical herniæ in infants to become cured by natural means. Therefore operation is not necessary before, say, 5 years of age. (*b*) Adult acquired: When there is present a large umbilical hernia in an obese woman, the question of operation is a serious one. It must always be remembered that there may not be sufficient room within the abdominal cavity for the contents of the sac. Cure of such herniæ by operation is most doubtful, but operation may make the condition such as to allow the wearing of a proper truss with comfort and safety.

4. *An Irreducible Hernia.*—There is no doubt that operation which allows of reduction of the contents of the hernial sac is ideal, but two points must always be very carefully considered: (*i*) Can all the contents find room within the abdomen? (*ii*) Will the operation permit of a truss being discarded?

Discussion on Indications for the Induction of Abortion.

By THOMAS WATTS EDEN, M.D.

(*British Med. Jour.*, Aug. 7, 1926, p. 237.)

It has never been possible to lay down strict rules as to the conditions under which abortion should be induced. Each case deserves consideration on its merits. It may at times be right to terminate pregnancy, even if the mother is not suffering from any condition which could strictly speaking be called disease, but as a rule when we advise the induction of abortion it is for some definite morbid condition which can be classed as disease. We should be prepared to terminate pregnancy in the early months whenever there is active pulmonary phthisis, except in the case of patients who are obviously dying; in cases of healed or arrested phthisis the whole circumstances should be reviewed in consultation with a physician before coming to any decision.

To women suffering from chronic nephritis pregnancy is always attended by certain very definite risks; breakdown of the renal function may occur leading to uræmic convulsions; an intercurrent attack of acute nephritis may supervene and supposing these complications occur and are survived, the working capacity of the damaged organs will be permanently reduced.

The fœtal risks are very heavy: probably not more than 60 per cent. of the children survive, death being due partly to prematurity and partly to the results of transplacental intoxication.

Notwithstanding these risks, it is possible for a woman with chronic nephritis to survive the ordeal of repeated pregnancy, and to produce a fair proportion of children who survive.

The hydræmic type, which is characterised clinically by dropsy, and in which the renal difficulty is in the passage of salt and water, is much more serious from our present point of view than the azotæmic type, in which there is no dropsy, but slowly progressive cardiovascular and retinal changes, and in which the renal difficulty is in the excretion of the waste products of metabolism.

Bacillus coli infection of the urinary tract in its subacute form does not lead to serious developments during pregnancy, although it is sometimes the cause of an acute outbreak of fever during the early puerperium which may closely resemble the onset of puerperal sepsis.

Diabetes Mellitus.—Although in the past we have regarded it as one of the gravest intercurrent diseases in pregnancy, with the resources of insulin treatment at our disposal its risks have been very greatly reduced, though not entirely eliminated.

The detection of sugar in the urine is not enough of itself to establish a diagnosis of diabetes. Glycosuria and lactosuria are not uncommon in pregnancy; they are not accompanied by an increase in the percentage of blood sugar, nor are they accompanied by the characteristic symptoms of diabetes, such as polyuria, thirst and wasting. A case of simple glycosuria is always amenable to dietetic treatment, and never forms an indication for abortion.

Valvular disease of the heart seldom calls for induction of abortion. A young woman with a well compensated valvular lesion will, as a rule, pass through one, or possibly two, pregnancies without suffering serious inconvenience. Repeated pregnancies, especially if they follow quickly upon one another, undoubtedly damage the heart and reduce the patient's expectation of life.

There are two types of case in which it may be right to induce abortion (1) the woman who in the early months of pregnancy shows signs of failure of compensation; (2) the woman in whom a previous pregnancy led to a serious cardiac breakdown.

Dr. Eden stated that he had terminated pregnancy on the advice of a psychiatric physician in one of the following sets of circumstances: (1) the patient had recovered from a previous attack of puerperal insanity; (2) the patient was what is called a "border-line" case, and had a bad family history. Such cases as these are pre-eminently suitable for team work, general practitioners or obstetric surgeons should not either alone or together assume the responsibilty for a decision. The whole of the circumstances of the case should be reviewed by the general practitioner, the psychiatric physician, and the obstetric surgeon in company.

Chorea is, as a rule, amenable to simple management by complete rest in bed (in a room apart), careful feeding, and the administration of arsenic. Occasionally severe cases are encountered, these are often obdurate, and it may be that termination of pregnancy may now and then be necessary in the pyrexial cases. In all others, no matter how severe the clonic spasm may be, induction of abortion need not be considered.

The obstetric indications are few and relatively unimportant. Toxæmic vomiting is that form of persistent vomiting in early pregnancy which is accompanied by definite signs of toxæmia, such as a heavy albuminuria, a raised blood pressure, pyrexia, and wasting; it sometimes proves to be incurable by medical means, and must then be arrested by terminating the pregnancy.

Toxæmic vomiting is rare, but other forms of hyperemesis are fairly common and are always amenable to medical treatment. The commonest form is the functional case which can be cured by segregation or simply by removal from home surroundings to the healthier moral atmosphere of a hospital ward. Induction of abortion is not to be contemplated in these cases which can be distinguished by the absence of the signs of toxæmic vomiting.

Vesicular mole, when diagnosed, is an invariable indication for induction of abortion. A presumptive diagnosis can be made from the syndrome which is fairly characteristic—namely, hæmorrhage, usually slight and continuous, over-enlargement of the uterus, absence of the physical signs which indicate a fœtus in the uterine cavity, and a characteristic semi-solid consistence of the uterus. If all these signs are present, the case is either one of vesicular mole or of a dead ovum with retained hæmorrhage. The treatment in either case is induction of abortion, and the circumstances are eminently suitable for the castor oil and quinine method of induction.

Missed Abortion.—The retention of a dead early ovum in the uterus is as a rule easily diagnosed, when an interval has elapsed which is sufficient to allow of shrinkage of the uterus.

Sooner or later the ovum will be spontaneously expelled and it very rarely becomes infected. It is, however, a source of annoyance and suspense to the patient. Here also the castor oil and quinine method is usually effectual.

Dr. Eden said that very free hæmorrhage in the early months of pregnancy does not, in all cases, result in abortion; we should never be in a hurry to interfere with a threatened abortion because it is attended at the onset by severe bleeding. Persistence of bleeding is of more serious import for the life of the ovum than an initial smart hæmorrhage.

Dr. A. Louis McIlroy dealt with three aspects of the question—the legal, the ethical and the therapeutic.

The legal aspect is that induction of abortion is always against the interest of the State, therefore legislative measures and precautions have been taken to prevent its performance except in cases of medical necessity. It is a criminal offence. The practitioner should make sure of his ground when confronted with a patient who is desirous of obtaining an interruption of her pregnancy. In all cases whenever possible he should secure a second opinion.

No social or economic interests apart from the medical needs of the case should be taken into account. We should not be influenced by any likelihood of defect in the character of the offspring. If the completion of gestation is undesirable for medical reasons, we should urge the avoidance of subsequent pregnancies, and the necessity for abortion at future dates would therefore be eliminated. If this course is impossible, the question of sterilizing the patient has to be discussed, and in some cases sterilization is the only course to be adopted.

When in doubt—?

SINCE the introduction of Dimol, the successful treatment of putrefactive and other bacterial invasions of the intestinal tract, and conditions arising therefrom, has been established beyond question.

Medical men are constantly reporting cases where Dimol has been especially effective, and describing conditions—until recently not associated with intestinal infection—which have been distinctly benefited by its use. This would seem to bear out the contentions of Charcot and Metchnikoff that 90% of all human ailments have their origin in intestinal toxaemia.

The careful practitioner, when in doubt, will bear this in mind now that we have a really efficient and non-toxic intestinal bactericide—*not a mere antiseptic.*

It must be remembered, however, that Dimol is not indicated in cases where the disturbance is of a purely chemical origin, i.e., where the causal agent is not a micro-organism; Dimol acts solely as a bactericide.

The efficiency of Dimol in the treatment of putrefactive and other bacterial invasions of the intestinal tract is conclusively told in the interesting clinical reports which, together with the brochure describing the chemistry and pharmacology of Dimol, will be sent to any physician on application to the

Reviews.

THE PRACTICAL MEDICINE SERIES: 1926 SERIES. —Edited by G. H. Weaver, M.D., and L. Brown, M.D. and others. Chicago: The Year Book Publishers, 1926. Pp. 738. Price, $3.00.

THE 1926 volume contains four parts:—

1. Infectious Diseases and Endocrinology.
2. Diseases of the Chest.
3. Diseases of the Blood and Blood-making Organs.
4. Diseases of the Gastro-Intestinal Tract.

Each of these parts is compiled by a separate editor, himself an expert on the subject he reviews.

In the Infectious Diseases' section recent advances in our knowledge of the exanthemata, encephalitis and meningitis are fully dealt with. In an interesting article it is shown how the national delicacy of the Americans—ice-cream—may broadcast scarlet fever. Under malaria the work done in the south of the United States is reviewed.

The abstracts of articles on endocrinology are full of useful information, goitre being dealt with at full length.

Under diseases of the chest, pulmonary tuberculosis receives adequate consideration.

In the third section—the anæmias and leukæmias—the diseases of the heart and blood vessels and kidneys are dealt with *seriatim*. The articles on heart disease are very valuable. Writing of the electrocardiograph in an article by Price in the *Practitioner*, the following summary of its usefulness is given. "It is the most precise means of investigating the functional efficiency of the myocardium itself. It gives fuller information in the vast majority of cases of cardiac disorders. This information is important in most cases and not infrequently it is indispensable".

In the fourth section there are many interesting articles abstracted which should be of value to both the surgeon and the physician. The articles on tropical medicine practically exclude the work done outside the American continent.

For a resumé of the progress made in medicine during the last two or three years in subjects which are being intensively studied in the United States this volume is to be highly recommended.

A MANUAL OF NORMAL PHYSICAL SIGNS.—By Wyndham B. Blanton, M.A., M.D. St. Louis: C. V. Mosby Company, 1926. Pp. 215. Price, $2.50.

IN most text-books on physical signs which come into the hands of the student the normal signs are given side by side with the pathological signs. This arrangement is liable to cause confusion in the mind of the student not familiar with the subject.

In this book normal signs only are summarised and in a few instances explained and discussed. There is no reference to signs of disease, but abnormalities—not necessarily associated with disease—are included. For the most part the author has adhered to a tabular arrangement for the sake of clarity and brevity.

This is a book that one would like to see in the hands of every second-year student. Twelve hours or so spent in intelligent assimilation of the contents would lay a foundation on which he could build for the rest of his medical career.

THE NATURAL PROCESS OF HEALING IN PULMONARY TUBERCULOSIS.—By Marc Jaquerod, M.D. Translated by J. D. Sinclair. London: Baillière, Tindall & Cox, 1926. Pp. 108. Plates 35. With 60 X-Ray figures. Price, 6s. net.

THIS excellent little work is profusely illustrated with radiographs, and for those who wish to learn to recognise the condition and the progress of the tuberculous lung by this method the book is to be highly recommended.

The author writes from a wide experience and some of his sayings are very illuminating. One such passage may be quoted. "In acute affections (typhoid fever for instance) the cure of the disease precedes convalescence. It is when the patient arrives at a state of exhaustion that his lesions heal and his general condition begins to improve. In pulmonary tuberculosis on the contrary, convalescence often precedes the cure of the local disease. The general condition may be excellent, while the lesions are still in full activity. Patients may be misled by this fact, and so endanger their prospects of cure. It is by being guided by the state of the lesions that it is possible to decide that the disease is cured."

Some thirty-one typical cases are described and radiographic photographs are given of each.

Great stress is laid upon the necessity of sufficient length of treatment; two years being given as the minimum.

Artificial pneumothorax is recommended in many cases whose "moral energy" prevents their taking so long an interval away from their work. The *conclusions* wind up as follows:—"As for ex-tubercular patients, they will do well to engrave on their memories the words of one of the greatest biologists of the day: 'Life is the maintenance of a constantly menaced equilibrium.' They will understand that what is true for healthy people applies with much more force to those who have once had this equilibrium seriously endangered, and have had the good fortune to see it re-established."

THE BEAUMONT FOUNDATION LECTURES. SERIES NO. 4. THE THYROID GLAND.—By Charles H. Mayo and Henry W. Plummer. St. Louis: The C. V. Mosby Company, 1926. Pp. 83. Price, $1.75.

THE subject-matter of this excellent book was delivered as the *Beaumont Foundation Lectures* (Series No. 4) under the auspices of the Wane County Medical Society, Detroit, Michigan, in 1925. It contains a complete resumé of the diseases of the thyroid gland, including a history of the literature on the subject, their geographical distribution, the anatomy and physiology and development of the thyroid gland, with studies in its biological chemistry and development.

The experience of both the authors in thyroid disease is indeed unique. They had an opportunity of studying over 22,000 cases of disease of this organism in all its phases during a period of 33 years. The pronouncements made in the book may, therefore, rightly claim to be authoritative.

The chapter on the etiology of goitre and the development of the thyroid is a very interesting study and the authors have ably discussed the various causation theories, chemical and bacteriological. The chapter on the parathyroid glands is well written and up to date. The hyper-thyroid states with their main clinical manifestations have received careful attention and this section will amply repay perusal. It gives us great pleasure to recommend this book to medical readers.

J. P. B.

ORTHOPÆDIC SURGERY.—By W. A. Cochrane, M.B., Ch.B., F.R.C.S.E. Edinburgh: E. & S. Livingstone, 1926. Pp. 528 with 504 illustrations. Price, Rs. 15-12 net. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta.

"THIS book is designed to give the student an understanding of the scope, principles and essential details of the speciality of the surgery of the locomotory apparatus in relation to the study of pathology and general medicine and surgery."

We consider that in this object the author has been unusually successful. The book is divided into two parts, the first part consisting of 87 pages devoted to the study of bodily mechanics and the results and treatment of faulty posture. This portion of the book is based on the author's experience as clinical assistant to Dr. J. E. Goldthwart of Boston, U. S. A.

Whether as a result of osteopathy and the other weird cults so prevalent in the U. S. A., more attention seems to have been devoted to this subject than in England where it has been left largely to the Eugene Sandow

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

and similar institutes of physical training. The importance of this question may be judged from the fact that out of 746 students entering Harvard University only 12.5 per cent. were found to use their bodies on good mechanical lines. In this section the author makes out a very strong case for physical education with reference to preventive medicine, and this first part might well be printed in separate pamphlet form and placed in the hands of all school medical officers and of those responsible for education. At the leading American universities the students are graded and physical education under a Professor of Physical Education insisted upon. They recognise that it is not worth while giving intellectual training to physical inefficients. Some day perhaps the Calcutta University will recognise the same fact, and will insist on physical efficiency in candidates for the matriculation examination. This part finishes with a detailed description of exercises and treatment of faulty posture.

The second part is devoted to orthopædic surgery as ordinarily understood. The whole field is well covered, and many rare conditions included. Each section is preceded by a review of the anatomical and functional considerations of the part concerned. The clinical descriptions are concise and sufficient, while the treatment is set out in detail, an important point, for in no section of surgery is attention to minute detail more important.

Only fractures in the region of joints are included, but these are described fully. For treatment, plaster of Paris is preferred to other splints. In treating joint affections the author emphasizes the necessity at the outset of deciding whether the ultimate aim of treatment is to result in ankylosis or in movement, and of immobilising the joint in the position of optimum function. This is not always the same for the two end results.

We can strongly recommend this book to all surgeons and medical practitioners.

PEDIATRICS.—By various authors. Edited by Isaac A. Abt, M.D. London and Philadelphia: W. B. Saunders Company, Ltd. Volume VIII. Pp. 1102 plus 388 illustrations and Desk Index to the entire work. Price, per set, cloth, £18 net.

THIS is the eighth and last volume of this great treatise on children's diseases. Fifteen experts have contributed to the volume, all of them being Americans, and most of them hailing from Chicago.

This volume maintains the same high standard as its predecessors. It deals with diseases of the skin, ear and eye: there is a chapter on hospitals, one on medico-legal work, one on tumours, one on encephalitis and one on animal parasites.

Skin diseases are classified according to cause when this is known. The article on hospitals for children is very complete; large numbers of plans of actual hospitals are given. Many of these are on lines which cannot be followed in this country, as the offices and administrative rooms occupy a large proportion of the buildings, and it would be interesting to know the cost of building and maintenance in some of the typical American hospitals. In India we are severely restricted by considerations of cost, so that American standards are quite unattainable.

It is quite impossible to review in detail all the sections of this volume. Obviously a great effort has been made to cover the whole range of children's diseases in the eight handsome volumes which make up the work, which will be welcomed as a valuable book of reference. The cost of the set is £18, so that the average practitioner can hardly hope to add it to his library.

HISTOLOGICAL TECHNIQUE.—By H. M. Carleton, M.A., B.Sc., D. Phil. Bombay, Oxford University Press, and Constable & Co., 1926. Pp. XV plus 398. Price, 16s. net.

THE object of this book is to give in as compact a form as possible all the details necessary for the histological examination of normal tissues and tissues which have undergone morbid change. The author would appear to have gone a little beyond his original intention—if this is reflected by the name he has applied to the book—and has described the technique for the examination of certain body fluids and dejecta for various pathogenic organisms.

In order to make clear the necessity for many of the steps that are taken in the fixation and preservation of morbid tissues, a detailed description of the cell as a structural and as a physico-chemical entity has been given. Part II consists of a description of various methods of fixation and section cutting and details of various staining methods. As the staining methods that have been employed are so numerous the author has not attempted to give a detailed description of every staining method, but has confined himself to a detailed description of "type" methods; this part of the book has been written in collaboration with Mr. F. Haynes. In Part III the author gives details of accessory methods, such as dark-ground illumination and vital staining. Part IV is devoted to the description of special histology; under a number of headings are given the methods which are suitable for each particular organ or tissue. The last part of the book is devoted to describing methods of demonstrating various histo-pathological processes and for the identification of various pathogenic micro-organisms.

This book meets a long-felt want. Much of the information which it gives is to be found elsewhere, but it is buried in large volumes on general pathology. The book is written so that the student can understand it and at the same time its simplicity does not irritate the experienced worker. One has little doubt that this book will find its way into every general pathological laboratory where the English language is spoken.

ANNALS OF THE PICKETT THOMSON RESEARCH LABORATORY.—Vol. II, No. 2, July 1926. London: Bailliere, Tindall & Cox. Pp. 175. Plates 40 (with 6 figures on each plate). Price 42s. net per annum. One volume per annum.

THIS number is for all practical purposes a monograph on the corynebacteria written by David and Robert Thomson. In addition there is a very short note on a Gram-negative organism isolated from certain cases of measles; this amounts to the conclusions on the work reported in the previous number of this volume. There is also a note by J. J. Thomson on the etiology of tuberculosis in relation to the satisfactory immunisation of cattle.

The article on the corynebacteria is a comprehensive one. There is a short account of the true diphtheria bacillus and of the various strains which have been isolated. The various diptheroids which have been described in the past are reviewed and a short account of each is given, together with the author's comments. This is followed by sections on the distribution of this group in nature and the pathological conditions with which they are associated. The various attempts that have been made to classify the diphtheroid bacilli and various difficulties that have arisen are reviewed. The article concludes with the author's suggestions for their classification with the aid of microphotography. The most important part of the whole number is the 38 excellent plates which include about 300 excellently reproduced photographs.

Annual Report.

ANNUAL REPORT OF THE HEALTH OFFICER, RANGOON, 1925. ANNUAL REPORT OF THE CONTAGIOUS DISEASES HOSPITAL AND THE MUNICIPAL OBSERVATION HOSPITAL, RANGOON, 1925. BY K. R. DALAL, L.M. & S., D.T.M., D.P.H., HEALTH OFFICER, RANGOON CORPORATION.

As usual, Dr. Dalal's annual reports are of considerable interest. The estimated population of Rangoon in

ARCANOL

combines the therapeutic qualities of **Atophan** with those of Acetyl-salicylic Acid so that **Arcanol** is

the Cure and Preventive of Influenza

and Catarrh of the Upper Respiratory Tracts.

Original Packing : Tubes of 10 Tablets of 15 grains each.

ATOPHAN

The Sovereign Remedy for Rheumatism and Gout

Immediate relief from pain and prompt cure in cases of **Acute** and **Chronic Muscular** and **Articular-rheumatism, Gout, Sciatica, Neuralgia, Lumbago, Neuritis, Pleuritis.**

In acute **Articular-rheumatism,** a prompt treatment with **Atophan** prevents **Heart-complications** with certainty, and all drawbacks of Salicylate-therapy are avoided.

Original Packing : Atophan Tablets tubes of 20 × 7½ grains each.
„ „ glass „ 500 × 7½ „ „
„ **Powder** 1-oz. glass.
„ **Dragées, Keratin-coated,** glass of 100 × 1½ grain.

ATOPHANYL

is a solution of the sodium salt of Atophan and Salicylic Acid for intravenous and intramuscular injection.

Original Packing : Atophanyl Intramuscular Boxes of 5 × 5 c.c.
„ **Intravenous** „ „ 5 × 10 c.c.

Samples and Literature on request from our Representative:

A NEW DISCOVERY

The Serotherapeutic Treatment of

ANAEMIA and HEMORRHAGE

by

HEMOSTYL

of

Dr. ROUSSEL (Paris).

The active element is the **serum** and the **blood** taken entirely from horses prepared by preliminary bleeding in a state of active hematopoiesis.

The **ampoules** contain 10 c.c. of pure **hemopoietic serum** to be injected with a little water in cases of anæmia, and to be injected pure in case of hemorrhage.

The syrup contains nothing but hemopoietic blood in a syrupy medium most agreeable and very soluble and is to be used for anæmia, chlorosis, etc.

The treatment with **HEMOSTYL is the only physiological treatment** of anæmia and is far more efficacious than the old methods with iron, hemoglobin, etc., etc.

Prescribed by 90,000 doctors in England, France, Spain, Italy, Belgium, Central and South America, etc., etc.

In April, 1925, there were at the "Institut de Serotherapie Hemopoietique of Romainville, Paris," 800 horses used for the production of serum.

1925 was 364,505, the birth-rate 18.76 and the death-rate (corrected for estimated population) 33.90 per mille. Still-births numbered 7.21 per mille of all births recorded, and the chief reason ascribed is the prevalence of venereal diseases.

Next to New York, Rangoon is the largest emigration and immigration port in the world, and its problems are especially concerned with a changing and migratory population. The low annual birth-rate recorded is due to several causes; (*a*) the excess of male immigrants over females, thus of the total immigrants in 1925, males numbered 2,99,022 as against only 31,190 females: (*b*) the fact that—as is usual in the big Indian cities—many married women go to their homes in the mofussil for their confinement; (*c*) defective registration of births. Infant mortality during the year was 351.85 per mille of births, and of 6,494 infants born in Rangoon Town 1,757 died within the first year of life, 637 of them within the first month. Premature birth, malnutrition and convulsions, and bronchitis and pneumonia appear to be the chief causes of the infant mortality; and there is a direct correlation between low economic conditions, bad and insanitary housing, and a high infantile mortality rate. Qualified midwives attended 48 per cent. of the births registered in the city during the year—a not inconsiderable figure.

Of the chief diseases plague shewed an increase to 724 cases as against 554 in the preceding year, with a case mortality of 91.16 per cent. Of 38,734 rats examined at the Corporation Laboratory, 119 were found to be infected, and the months of March and May shewed the highest incidence of plague among the rats of the city. The human disease was at its height in April, and Hindus were especially affected. The usual measures were taken; 1,077 persons were inoculated, 32,802 houses cleaned and 2,935 disinfected. Eighteen permanent and 8 temporary gangs were engaged in site-cleaning and intensive ratting in *kutcha* areas, and in all 604,250 rats were destroyed.

Cholera was unimportant during the year; 82 cases as against 167 in 1924. Small-pox, however, assumed epidemic proportions during the first 5 months of the year, and 1,956 cases occurred, of which 228 were imported. The small-pox death-rate per mille was 1.83 as against an average of 0.41 for the previous 5 years. The epidemic reached its height in March, when 741 cases occurred, and an extra staff of 12 vaccinators was engaged. Vaccinations totalled 127,111, of which 32,345 were carried out during February.

Influenza was unimportant during the year, whilst a definite increase in incidence of enteric fever occurred. Diarrhœa and dysentery were especially prevalent, and investigations were carried out to ascertain why. The water-supply from the Hlawga Lake was proved not to be responsible, whilst samples of milk, fish, fruit and lettuce from various sources were examined with negative results. Wells and tanks however constitute an important part of the water-supply and these become infected in the early rains, whilst flies and the insanitary state of milkstalls and foodshops contribute. The greater part of the city is still dependent on tub latrines for its conservancy, and although the tubs are emptied daily they are in a grossly insanitary state.

Tuberculosis shewed a definite increase, with a high incidence amongst Buddhists. Other respiratory diseases accounted for a mortality of 6.78 per mille, and these diseases are especially prevalent among the population engaged in river traffic, poorly nourished, ill-clad, and often working in inclement weather. Beriberi caused 60 deaths, of which 50 occurred among Hindus; 6 cases of epidemic dropsy with one death occurred among the shipwrecked crew of a native craft wrecked at sea and picked up and landed at Rangoon by the S.S. *Ellora*. Twelve deaths from kala-azar were reported.

Turning to the hospitals and dispensaries, 2,731 cases were admitted to the Contagious Diseases and Observation Hospitals. The daily average outpatient attendance at the Dalla Dispensary was 60.5, at the Kanaungto Dispensary 63.0, at the Theinbyu Dispensary 97.0, and at the Forest Road Dispensary 48.2. A proposal to attach a small dispensary to each registration and vaccination station in the town was negatived, each case for a new dispensary being thought to require consideration on its own merits. There are eight such registration and vaccination stations in the town.

The Corporation Laboratory carried out 39,521 bacteriological and 239 chemical examinations during the year, and a very large amount of foodstuffs including 27,328 bundles of jerked meat was condemned and destroyed. The annual meat show was held on Xmas Eve and monetary prizes to the amount of Rs. 650 awarded. An annual cattle show was also held during the same month, and prizes totalling Rs. 1,690 were awarded. The Burma Agricultural Department awarded a special prize for the best Burma-bred sheep. Reclamation works are in progress at Theinbyu and Dufferin Garden, and the work at Saline Monastery was completed.

In his concluding general section, Dr. Dalal has remarks of general interest to make on the special public health problems of Rangoon:—

The principal causes of the insanitary conditions which maintain the death and sickness rate at a high level in our city, excluding the annual recrudescence of such epidemic diseases as plague, cholera and small-pox are (1) the absence of a wholesome and abundant pipe water-supply in some parts of the town and insufficient supply in the rest; (2) absence of proper drains and sewers; (3) the existence of the large number of tub latrines, (4) the extreme over-crowding of houses in the town; and (5) the high density of population per acre.

The bacteriological reports on the purity of our Hlawga Lake water have ever been a source of grave anxiety to the officers concerned, as this lake water is being distributed to the public without any preliminary treatment for its purification.

The total count of micro-organisms found present in one c.c. of the sample examined, has always given too high a figure for good potable water. Occasionally the results have revealed the presence of micro-organisms of non-resistant types indicating some recent pollution of water by human or animal fæcal matter. So far no disastrous results have followed the presence of such micro-organisms, but such a fortuitous event may only be due to the pollution of the said water at the time by some innocuous excreta. Disastrous results would certainly follow if the chance pollution were to take place by some specific pollution as from a case of enteric, cholera or some other waterborne diseases. Besides the catchment area and the lake itself are so easily accessible to passers-by, trespassers and poachers that a tremendous risk is taken every day against any chance contamination of the water with specific and non-specific pollutions. It is impossible to keep stray men and animals from entering the lake area.

With the existence of the new cantonment area within easy reach of the Hlawga Lakes and the concomitant growth of the village and traffic near by this danger would soon become a more potential one.

The use of chlorine is the cheapest method of purifying large quantities of water for our town supply, the most efficient process by which the removal of bacteria could be accomplished, and the most economical in its working cost. Much advance has been made in the chlorination plant where liquid chlorine gas can be regulated to the minutest degree to suit whatever percentage is required for any particular water.

I would therefore strongly recommend that early steps be taken to instal an efficient chlorination plant either near Pegu Pumping Station or the new reservoir to render our lake water-supply epidemiologically safe.

As for the quantity of water available, unless some immediate steps are taken to explore new and practicable avenues to secure a wholesome and ample supply of water, the city will have to face in the very near future problems of very grave importance. Hardly one half

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of the present population has been supplied with pipe water, the remaining having been left to the tender mercies of wells, shallow, deep or tube. The town is being extended far and wide. New areas have been reclaimed and laid out, new workshops, factories and extensions are going on *pari-passu* and the consumption and demand for water has greatly outgrown the limited supply at our disposal.

There is such a free communication of our town by rail, river and road with other infected districts of the Province that almost all the cases of cholera first noticed in our town, are imported from outside and it needs the utmost vigilance on the part of the Health Department to control and prevent the outbreak of this disease into more serious proportions in the city. But the standing menace of such an unfortunate incident in the future is there all the same so long as the whole town is not supplied with wholesome and abundant pipe water.

Infantile Mortality.—Practically speaking in our town for every 3 babies born, one dies before it reaches the first year of life.

Poverty, ignorance, insanitary dwellings and injudicious infant feeding are the principal causes of high infantile mortality in every city, but not a little is contributed by the mother before the child is born, as the health and life of the new-born infant very greatly depend upon the health, care and attendance given to the mother before, during and after confinement.

The measures for the reduction of infant mortality group themselves under maternity and child welfare centres which should comprise the following:—

(1) Home visiting by lady health visitors for finding out prospective mothers, cases of sickness among mothers and infants, enquiry into the condition of the new-born infants and instructions by homely talk on sanitation, cleanliness, domestic hygiene and breast-feeding.

(2) Maternity homes and shelters for the poor.

(3) Free attendance by qualified midwives on confinements at home of the poor of the purdah-nashin women who would not go to the shelter during the lying-in period.

(4) Free provision of necessaries and comforts.

(5) Infant milk depôts for cheap or free distribution of pure milk to infants and children of the poor up to the age of 18 months.

(6) Infant welfare centres where the sick infants of the poor are admitted and treated.

(7) Antenatal clinics to give proper care and treatment to the expectant mother.

The Society for the Promotion of Infant Welfare in Rangoon under the fostering care and able guidance of Lady Giles has been carrying on much good work in Rangoon, but much yet remains to be done.

It has been a matter of great regret that our city does not possess a single maternity and infant welfare clinic where prospective mothers may receive the care and attendance needed during the most critical period of their life and where antenatal care of the infant to be born may be taken.

Plague.—During every year of the epidemic, it has been observed that plague first makes its appearance in the *kutcha* quarters of the town such as Kemmendine, Theinbyu and Pazundaung at both ends of the land and taking root in these quarters it gradually spreads more and more towards the centre of the town where it at last exhausts itself for the year in this *pucca* area. As is well known plague, rodents and rubbish are intimately connected to each other. Theoretically, therefore, if we could exclude the latter two, we can exclude plague automatically.

There are large tracts of land beyond public roadways and back drainage spaces which can never be attended to by our present conservancy staff. Similarly all private lands leased out to poor tenants who have built structures 4 feet off the site. All such places are usually found seething with filth and rubbish of every description. Action certainly could be taken under the Act against the owners or occupiers of these lands, but the enormous amount of time and energy wasted in issuing notices, frequent inspections and prosecutions of the parties concerned, who are mostly extremely poor, is hardly commensurate with the result obtained. The sense of health conscience has not as yet been awakened in the general public and it should form part of our duty for the present to undertake removal of all filth and rubbish from all such lands. It would obviously necessitate a big increase in our conservancy staff but the results so far achieved, even by the entertainment of eight extra gangs during the year under report in not only preventing a much apprehended severe incidence of plague epidemic but reducing the number of cases of plague much below the normal years even, justify our incurring any expenditure however heavy in this connection.

Small-pox.—The prevalence of epidemic small-pox has unfortunately become an event of perennial occurrence in our city. Year after year the same woeful tale is told of the sad havoc caused by this disease. Every few years a more virulent wave of the epidemic swoops over the town claiming a heavier toll of human life than the usual. The conditions under which the large majority of the labouring class live in the town, the extreme over-crowding in the living rooms and the very large number of the unprotected people in the population afford excellent field for this disease to spread like wildfire. The condition of our city is unique. The migratory population of the town is enormous. Our city next to New York is the largest immigration port in the world. The permanent population of the town is hardly one-third of the total.

Moreover this huge labouring population is forced by circumstances to live in over-crowded, ill-ventilated, insanitary houses, huts and hovels, and the ignorance, poverty and misery inseparable from these unfortunate people only render them more vulnerable to any infectious or contagious disease. There will be few towns in the East or West where vaccination propaganda is carried out to such an extent as in our town.

Another great factor in the annual recrudescence of small-pox in our city is the very large number of cases imported into the town.

Had it not been for the brilliant success achieved by the intensive campaign of vaccination and re-vaccination that was launched during the year under report wherein over 1,27,111 persons were vaccinated in spite of the fact that we were greatly handicapped in the absence of any Act for compulsory re-vaccination, the last serious epidemic would have assumed more virulent and widespread proportions and entailed untold suffering, misery and death.

One of the most important functions of a Health Officer is the intelligent anticipation of the probable course of an impending outbreak of an epidemic disease. The history of small-pox in our town has revealed one outstanding feature of the course of events that follow its annual recrudescence. As noted in the Annual Report for the year 1923, a periodic wave of the epidemic of small-pox of greater virulence breaks out every fourth year or thereabouts preceded and followed by an outbreak of moderate intensity. The first signs of such an impending epidemic were noted in the month of November 1924, and anticipating this periodic wave to occur in the year under report, precautionary measures were taken in time and sanction was obtained in December 1924 to entertain a large staff of temporary vaccinators and an intensive campaign of vaccination and re-vaccination of all the labouring population of the town, which by the way is the predominant one not only in number but in the suffering and spread of the disease, was started with the result that a very large portion of the population constantly exposed to infection was protected in time and further spread of the disease was rapidly checked by the end of March, within 3 months of its first outbreak. The last wave of the epidemic was also of the classical type with a heavy case mortality rate of 31.47 per cent.

THE discovery of the new synthetic remedy for the treatment of Cystitis, Pyelitis, and other infections of the urinary tract

'CAPROKOL'

(Hexyl-Resorcinol)

marks a new epoch in the treatment of all bacterial infections of the kidneys, bladder and the urinary tract. 'Caprokol' is non-toxic, stable administrable by the mouth, and has forty-five times the bactericidal power of phenol.

It is excreted unchanged by the kidneys in sufficient proportion to impart active bactericidal properties to the urine.

'Caprokol' is supplied in flexible gelatine capsules, each containing 0.15 gram 'Caprokol' in olive oil solution, and in 4-oz. bottles containing a 2½ per cent. solution of 'Caprokol' in olive oil.

'CAPROKOL' (Hexyl-Resorcinol)

is manufactured under **sole** British Licence from the Patentees, Messrs. Sharp & Dohme, Inc., Baltimore.

The Elimination of Uncertainty

AGAROL is the *original* Mineral Oil—Agar-Agar Emulsion, and has these special advantages: Perfectly homogenized and stable; pleasant taste without artificial flavouring; freedom from sugar, alkalies and alcohol; no contraindications; no oil leakage; no griping or pain; no nausea or gastric disturbances; not habit forming.

AMONG the newer remedies of proven worth, there is hardly one that has won the favour of conservative medical men to so certain or complete a degree as

AGAROL

The chief reason for this is undoubtedly found in its remarkable reliability of action.

A great many practitioners have expressed their appreciation of the palatability of Agarol, especially the complete absence of oily or greasy taste. Others have remarked on its gratifying freedom from any griping, discomfort, or anal leakage. But report after report has emphasized the uniform efficiency with which it has produced the results desired.

A moment's consideration of the composition of Agarol—with its carefully balanced proportions of pure mineral oil, agar-agar and phenolphthalein—followed by a practical clinical test, will convince the most critical practitioner that here is no ordinary laxative, but a rational physiological corrective that offers far-reaching possibilities in restoring regularity of the bowels.

I need hardly draw attention once again to the very grave risk involved in allowing unprotected immigrants to enter the Province and the danger of infection from these immigrants. To my mind the only rational procedure would be to pass an Act making it obligatory to vaccinate every labouring hand before he is allowed to enter the Province. Under the existing conditions it is practically hopeless to protect the town against the visitations of this annual scourge as whatever the precautions taken or other preventive measures adopted such as isolation, segregation, disinfection, etc., they will be of very little avail under the prevailing conditions in the East and are no substitutes for vaccination.

Correspondence.

TROPICAL TYPHUS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The article on tropical typhus by Fletcher and Lesslar in the *Indian Medical Gazette* for November 1926 is of great interest.

While I was Agency Surgeon in Gilgit I saw a number of cases of fever which gave me food for thought. When I first made the acquaintance of the inhabitants of the Agency I asked if typhus was prevalent and was told that it was unknown. I very soon came to the conclusion that it was unknown because it was undiagnosed. I saw enough cases of a disease which was clinically typhus to convince me that it was typhus modified, so I thought, by endemicity and partial immunity. Two absolutely typical cases in British officers confirmed to my own satisfaction the diagnosis of the cases in Indians.

In the cases of the British officers there was no opportunity of spread among Europeans, for in one case all precautions were immediately taken and in the other, except myself, no other Europeans were within 50 miles. It is true that Indian servants were to some extent exposed to possible infection, but none of them developed any symptoms.

One other case occurred in a non-native of the Agency. The patient was an Indian gentleman whom I did not see during the acute stage of his illness but of whom I had daily reports. I have no doubt that he too suffered from the same disease.

In the case of the British officers the disease was perfectly typical, and though both were fairly seriously ill for a time, convalescence was rapid and there were no complications or sequelæ. The Indian case was more prolonged and he subsequently suffered from boils and loss of hair with considerable debility for some time.

There was never any epidemic. This I attributed to the fact that the Europeans and the Indians were in no way protected, whereas the natives of the Agency had contracted a certain resistance to infection.

Of course in a practice such as the Gilgit Agency only a proportion of fever cases is ever seen by the Agency Surgeon or even by subordinate medical officers, so the actual frequency of the condition above referred to is unknown.

It is at least possible that the cases I refer to were distinct from typhus proper, and of the nature of those described by Drs. Fletcher and Lesslar.

Rats, lice and ticks abound in the Agency, though in none of my cases was there a history of bite. All my cases were seen during the summer months.

May I, at the risk of unpopularity with the compilers and readers (if any) of statistics, put in a plea for more interest in "fevers"? A satisfactory "return" must contain a list of surgical operations—successful or otherwise. Nobody worries about the countless cases daily recorded in the out-patient register and treated (save the mark) with a dose of quinine or magnesia. Might we not only advance our knowledge but also possibly save some unfortunates from the operation table if medical subordinates were encouraged to *diagnose* cases of "fever"?

I saw in Gilgit in the summer of 1925 two cases—Europeans—of a disease, which, though remarkably like typhoid, was, to my mind, definitely distinct. Notes of these cases I sent at the time to the Superintending Surgeon, Jammu and Kashmir State, and I believe they will be published shortly.—Yours, etc.,

TREATMENT BY SUGGESTION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—There is probably no subject within the four corners of "medicine" that is so consistently neglected, misunderstood and maligned in equal proportions as that of suggestion, hypnotism, mesmerism, Braidism, Couéism, or whatever name the particular critic prefers to apply to a most interesting branch of psycho-therapy. Broad dogmatic statements are made, usually by authorities who have no personal and practical knowledge of the matter with which they are dealing.

"Suggestion" is not the only sufferer in this regard. Looking back, we find that Harvey was abused, Simpson was adversely criticised, Laennec was laughed at, Lister was maligned; so the suggestion-*wala* is at least in good company.

As I write, there lies on my desk a ponderous volume (American) open at a chapter the heading of which is "Mental Disorders in Medico-Legal Relations," with the sub-title "Disorders of Consciousness."

Amongst other statements, the distinguished authors make themselves responsible for the following expression of opinion, in proof of the soundness of which they refrain from bringing forward any evidence whatever.

"It would be impossible for one under hypnotic influence to exert normal inhibitions against a suggested act, and such an act committed in hypnosis would have the quality of an irresistible impulse. Our knowledge regarding hypnotic states is almost entirely from laboratory experiment and clinical studies in non-forensic relations. In such observations it is difficult to arrange an experiment that would correspond to the requirements of an actual act having serious criminal importance." I think the fair minded man will agree that these statements practically antagonise one another, especially if the word "impossible" is substituted for "difficult" in the second statement. Seeing however, that it is quite possible to observe the action of the normal inhibitions at work even in the hypnotic state produced for curative purposes, we, whether as general practitioners or as medical jurists, can make up our minds on the subject after proper investigation. The complaint of the practitioner who uses suggestion in the course of his work is that the medical profession makes no effort at the proper investigation which the obtainable results will amply repay.

As an ounce of practice is more valuable than a ton of theory, a short description of a recent case sent to me for treatment by suggestion may give your readers "to think." A young woman aged about 20 was admitted to hospital for treatment of a non-specific vaginitis. The development of mental symptoms (attacks of violence, insomnia, etc.) drew attention to her previous history. Deserted by her husband, she had indulged in loose living, and finding the same remunerative, had become to all intents and purposes a prostitute.

Treated by suggestion, her mental and physical conditions improved very rapidly. She became cheerful, ate and slept well, became truthful and industrious. Deep hypnosis was easily induced on each occasion and post-hypnotic suggestions were carried out to the letter with one important and instructive exception. She had expressed her intention to go to a distant city. It was ascertained that she had arranged to occupy a flat in that city for the purpose of her business, and that several prospective clients were expecting her return at an

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

early date. Any suggestion given to her in deep sleep, that she should not go to the city in question, that she should lead a moral life, that she should remain in the Home in which she was being treated during her convalescence, resulted in the production of an angry frown, an impatient movement, or a tendency to awaken. All other suggestions, tending to her physical and mental well-being were accepted and transformed into fact, the suggestion of moral reform being contrary to her express and expressed desires alone being rejected.

I could multiply such instances, e.g., in cases of dypsomania, drug taking, etc., where the patient at heart does not wish to be cured, suggestions are but temporarily accepted or are rejected, even in deep hypnosis, the induction of which is rare, and usually unnecessary. No thinking man who examines the matter will find it difficult to believe that "it would not be impossible for one under hypnotic influence to exert normal inhibitions against a suggested act," in cases where the suggested act, whether good or evil, was contrary to the subject's beliefs or prejudices, or inimical to his interests.

The old adage says that "a little knowledge is a dangerous thing." I think, Sir, that you will agree with me that no knowledge at all is very much more dangerous.—Yours, etc.,

WILLIAM NUNAN,
Police Surgeon, Bombay.

29th December, 1926.

THE TREATMENT OF SNAKE-BITE.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Referring to Dr. Banerjee's letter in the October 1926 issue of the *Gazette*, I would refer him to Wall's book on the *Poisonous Terrestrial Snakes of India and Ceylon*, published by the Bombay Natural History Society, in which book the symptoms and treatment of snake poisoning are gone into very thoroughly. Dr. Banerjee's statement is quite correct that sloughing may be produced by the venom itself, but by the rubbing in of permanganate crystals the destruction of tissue is much greater and the production of sloughing not an uncertainty, while the wound resulting is much larger and takes longer to heal than if the venom injected had not been assisted by the caustic in its destructive effect. Let me quote Wall on this point: under medicinal preventive treatment he says "various agents are known to neutralise snake venom when mixed with it in a vessel, a chemical decomposition arising which robs the venom of its poisonous qualities. Such are permanganate of potash, chloride of gold, silver nitrate, the chloride and hypochlorite of lime, etc. When Fayrer (in 1869) first discovered that permanganate of potash possessed this property there was theoretically every reason to suppose that it would prove antidotal when introduced within the tissues holding the snake venom, but experiment proved otherwise. What is true of permanganate of potash is probably equally true of the other substances enumerated. Snake venom when once introduced into living tissues is locked up in them so tenaciously that it can only with great difficulty and then only imperfectly, be brought into chemical relationship with neutralising agents of this class.

Col. Bannerman has convincingly shown from a large series of experiments on living animals that permanganate is for all practical purposes of little, if any, avail. In these experiments, some of which I witnessed, the tissues were cut into after the injection of venom by a hypodermic syringe specially fitted on to the fangs of a Russell's viper, thoroughly opened up and permanganate was then (within a second or two) rubbed into the incised wounds. The circumstances were obviously far more favourable than could possibly ever obtain in a bitten subject in medical practice, yet the salt rarely reprieved the death sentence." This sounds convincing, being based on accurate scientific observation, and not on tradition.

As regards the depth of incision necessary, since in the vipers the poison fang is much longer than in the cobra and rarely exceeds half an inch even in the largest specimens of vipers * it is obvious that the indiscriminate infliction of incisions in various parts about the affected locality, and the great depths of some of these incisions, often down to bone, equally merits the stigma of bad practice as does the administration of alcohol in ophitoxæmia.—Yours, etc.,

J. E. LEONARD CHINAL,
M. D., D. T. M. (*Bengal*).

MONGHYR,
10th December, 1926.

QUININE UREA IN MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Referring to your note to my letter in the November 1926 issue of the *Gazette*, you appear to have missed my point when you state "in hydrophobia the use of any remedy which may be of value in heroic doses is legitimate." What I attempted to draw attention to was the safe use of such large doses of the quinine preparation mentioned without any harmful effects, and from this I naturally felt that there are other possible uses of quinine urea than its employment only as a local anæsthethic.

Then again Major Chopra states that quinine urea solutions are strongly acid and cannot be used subcutaneously, but are the other quinine salts used by the parenteral method any less acid? Quinine urea has lately been used in 1 per cent. solution intramuscularly in acute lumbago, and even into the gums for extraction of teeth; perhaps some day it will be found of use in certain cases of malaria, either intramuscularly or intravenously in proper dosage and solution.—Yours, etc.,

J. E. L. CHINAL,
M. D., D. T. M. (*Bengal*).

MONGHYR,
10th December, 1926.

INFANTILE CIRRHOSIS OF THE LIVER.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the observations made by Dr. A. S. Vaidyanatha Iyer, in the *Indian Medical Gazette* for December 1926, regarding infantile cirrhosis of the liver, while thanking him very much for the valuable information given to the readers of the *Gazette*, may I request him to kindly enlighten me on the following doubtful points.

(1) Whether a post-mortem examination was made in any of the fatal cases, and if so the result of the microscropic examination of liver sections confirming the diagnosis of cirrhosis.

(2) Considering that rickets, a disease of metabolism, is due also to faulty digestion and assimilation of an unsuitable and deficient diet and as its manifestations are many and varied and not confined to the bones alone, and as it may also happen that the bone changes may be masked by other symptoms, and as the symptoms described by him closely resemble those of an ordinary case of rickets in its early stages—except jaundice as seen in the late stages of his cases—the other signs and symptoms, including the enlargement of liver and spleen being also met with in rickets, what are the distinguishing features of rickets and cirrhosis of the liver in their early stages? In this connection, I may also add that the age incidence of rickets is also the same as that found by him, the onset being generally after 6 months of age. Cases of infantile cirrhosis of the liver due to congenital syphilis or due to congenital obliteration of the bile ducts manifest symptoms of jaundice either from birth or immediately afterwards and they are invariably fatal. The cases cited by Dr. Iyer do not in any way conform to any of these conditions.

On reading over again the observations made by Dr. Iyer and also the particular line of treatment adopted, I am even lead to wonder whether some of his cases

For Emergency Conditions

Bovril is known to the medical faculty as a rapid restorative. Its stimulating and strengthening effects are particularly useful because of the rapidity of its assimilation and of its resulting power to support the patient in case of threatened collapse.

Bovril is the concentrated essence of beef. It is a nutritive food as well as a valuable stimulant, and its body-building powers have been proved by independent scientific investigation to be from 10 to 20 times the amount taken.

Micro-photograph of stool after Petrolagar administration, showing complete emulsification and thorough admixture with intestinal content.
(1) *Epithelial Cells*, (2) *Microscopic Oil Globule*, (3) *Agar-Agar Granule*, (4) *Faces*.

Micro-photograph of faces after administration of plain mineral oil, showing complete absence of emulsification: this explain why mineral oil always leaks.
(1) *Epithelial Cells*, (2) *Oil Globule*, (3) *Faces*.

Petrolagar

(DESHELL)

FOR CONSTIPATION.

THE micro - photographs clearly demonstrate the superiority of Petrolagar over ordinary liquid paraffin in the treatment of constipation. On the left the perfect admixture with the intestinal content obtained with Petrolagar is apparent; the other photograph, in which large unemulsified globules of oil are present, explains at a glance why plain mineral oil never has solved and never can solve the problem of constipation. It also shows why mineral oil leaks.

The drawbacks inseparable from the use of plain liquid medicinal paraffin are well known. Many patients cannot tolerate its insipidity; digestive disturbances sometimes occur; whilst thorough admixture with the intestinal content is seldom attained, with consequent leakage from the rectum.

Petrolagar contains 65% of purest mineral oil with a 10% Agar emulsifying agent, prepared from 1½% anhydrous agar, forming a perfectly stable, homogeneous and highly palatable emulsion.

There is no taste of oil, so that the most fastidious patients take the product readily. In the treatment of chronic constipation, Petrolagar gives results unobtainable by any other method and breaks the vicious circle set up by the habitual use of drastic purgatives. The medicinal paraffin is so finely divided that it is thoroughly disseminated throughout the fæcal mass, thus leakage is almost entirely eliminated; the agar-agar is specially prepared so as to yield on incubation in the intestinal tract many times its original bulk, forming a bland gelatinous mass which is completely and readily eliminated, acting indeed, as a soothing emollient to the inflamed intestinal mucosa.

As contrasted with cathartics, Petrolagar is non-habit forming, and once normal elimination has been restored may be given in diminishing quantity.

Issued in One Pound Sizes as follows:—

EMETINE ADMINISTRATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I have read with interest the article which appeared in your October 1926 number concerning paresis following emetine injections by Dr. B. D. Pal, M.B., B.S. I have treated not only amœbic dysentery cases but also many other kinds of intestinal disorders with emetine hydrochloride injection, and my experience of emetine injections is contrary to Dr. Pal's, as I do not follow his method of introducing this drug into the human system. First of all I would like to mention the drawbacks which emetine possesses; many patients tolerate only small doses which are not enough to bring about a complete cure. Larger amounts sufficient to effect complete eradication of the parasite produce marked tachycardia, vertigo and vomiting. To withstand this a weak patient has to be given cardiac stimulants before the emetine medication. Amongst other signs of its toxicity the following are mentioned; weakness of the muscles of mastication, deglutition and speech, paralysis of smooth muscle fibres and of the vaso-motor centre, with a fall of blood pressure and syncope. To avoid these toxic effects my method of emetine administration is as follows. I do not inject into the muscle fibres but give a first subcutaneous dose of gr. ½ in 20 m. of distilled water in the lower third of upper arm posteriorly; the second dose gr. ¼ in 20 m. of distilled water I give directly into the vein until I have given 6 grs. by the vein, preferably on an empty stomach and during the morning hours. I have experienced no such toxic symptoms as are reported by many and in particular by Dr. Pal.—Yours, etc.,

A. DAWSON, L.M.P.,
Medical Officer, Thonze.

15th December, 1926.

THE OPERATIVE TREATMENT OF FRACTURES.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In his letter which was inspired by my article on the operative treatment of fractures in the September 1926 issue of the *Indian Medical Gazette*, Colonel Proctor accuses me of "ridiculing the present accepted methods of treating fractures." I have never ridiculed the present accepted methods of treating fractures; what I did ridicule was the practice of traumatising the tissues at the site of the fracture under anæsthetic, followed by the application of plaster of Paris. I am happy that Colonel Proctor has given me another opportunity of denouncing this obsolete folly and cruelty. Colonel Proctor's letter abounds in dogmatic and *ex-cathedra* statements. "Surgical opinion has long since crystallised out." "As far as India is concerned we may leave it at that." Leave it at what? At a method of treatment which was in use in the time of the Pharaohs? Such a practice has the respectability which only antiquity can confer, but none but the most unsophisticated can be expected to accept it as up to date. If Colonel Proctor will consult Professor Hey Groves's comprehensive work on the treatment of fractures he will find this very practice mentioned, only to be condemned. He will find that he is advised to wrap a piece of stick up in a number of layers of cloth, to fracture it, to displace the ends, and then to endeavour to replace them again. His lack of success will convince him of the futility of his attempts to "set" fractures by manipulations under an anæsthetic. He will find an excellent resumé of the whole subject in the latest edition of Rose and Carless's *Surgery*, a work available to every medical student. If he reads this, he will learn that it is possible to obtain results in the treatment of simple fractures without that deadly double offensive of gas and trauma. I am not for the moment discussing the operative treatment of fractures. I am meeting him on his own ground, in the province of the non-operative treatment of simple fractures. He will obtain (I trust) a firm grasp of the two great principles which underlie the modern treatment of simple fractures, namely relaxation of the muscles by flexion, and extension in the line of the limb by a weight sufficient to overcome the pull of the muscles. These principles have emerged solid and unassailable, fortified by the immense experience accumulated in the treatment of fractures in the Great War. He will find, if he will apply these methods, that it is possible to obtain almost perfect restitution of the form of the bone by the gentle but powerful operation of adequate extension combined with muscular relaxation. He will find that all this can be effected without the infliction of any trauma or without the administration of even a whiff of chloroform. He will find that the practice of which he is the champion has long since been consigned to the lumbar room of obsolete methods.

Now since I never willingly allow a misstatement to go by default, I must correct the various errors contained in Colonel Proctor's letter. No one—least of all myself—advocates the practice of leaving plates on the growing ends of bones. This is a misstatement and I challenge Colonel Proctor to quote anything that I have written in support of it. A large number of these fractures are above the line of growth; where they are not so the plates would of course be removed. I cannot say that I am greatly impressed by "the revolt against the general use of metallic sutures and plates." It is not dignified or logical to revolt against a method of treatment which is admirably successful in competent hands, because one naturally asks, was the revolt founded on a disastrous series of cases in the revolter's own practice. Let us hear the conclusion of the whole matter. If the surgeon's technique is not good enough to secure aseptic results, he should leave bone plating alone and rely on other methods. He should, however, be sure that these methods are really up-to-date before taking on himself the responsibility of criticising his brother. In conclusion I must express my regret for not replying earlier, but my attention has only just been drawn to Colonel Proctor's letter.—Yours, etc.,

H. HALLILAY,
LIEUT.-COLONEL, I.M.S.,
Civil Surgeon.

AMRITSAR,
3rd January, 1927.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I expressly stated in my letter that I did not intend to enter into a controversy as to the merits of the operative treatment of fractures. Colonel Hallilay's letter makes it clear that he is not ridiculing present accepted methods of treatment. His article left myself and others with the impression that he was ridiculing all non-operative treatment. For that I think his unique literary style must be blamed.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Had I not wished to avoid a controversy I should have enumerated the principles of flexion, extension, suspension, early active and passive movements, etc. Colonel Hallilay admits that by applying these methods it is possible to obtain almost perfect restitution of form and, I may add, of function. If so, why in season and out advocate plating? Surely this is argument enough for such a strong opponent of traumatism under an anæsthetic.

It was precisely because I was acquainted with these facts that I ventured to criticise Colonel Hallilay's article.

I expressly stated that his thesis was that "All fractures should be plated." He himself states "..... no one who is not hopelessly prejudiced can deny the overwhelming superiority of the method of open operation."

If I have misunderstood him, and his position is that open operation—not necessarily plating—is indicated in cases where these non-operative measures have failed, or where we know by experience they will fail, then I shall be glad to agree with him. I have however up to this letter found nothing in his writings or in his notes of cases to indicate this.

Colonel Hallilay assumes that the revolt against the general use of metallic sutures and plates is founded on disastrous results. It is nothing of the sort, and if he is acquainted with modern fracture literature he knows it. It is based on the fact that the chief contra-indication to operation is that it is not necessary. I ask your surgical readers to carefully study his skiagram 2. We may assume it is taken so as to show the maximum deformity. Is there any indication for plating this fracture in a child of seven? A perfect anatomical and functional result is even more certain without an operation. By the way, the word "revolt" is not mine but that of one of the greatest authorities on fractures. Colonel Hallilay takes me to task for accusing him of advocating leaving plates on the growing ends of bones. I made no such statement, but that in practice he had left plates on the growing ends of bones.

Turn to the case of Rashik Mohan, case 6 of fractures into the elbow joint.

This case aged 11 had a T-shaped fracture into the elbow joint. We know that in such cases the line of fracture runs just above but only just above the epiphyseal line. Two plates and 8 screws were used, and one need only look at the humerus of a child aged 11 to realise that at least one or more of those eight screws must have involved the epiphysis, yet there is no record of the plates having been removed.

Again, Kenneth Cole, aged 15, a Colles' fracture, controlled by a plate and 6 screws. A Colles' fracture lies between ½ inches to 1 inch of the articular margin and close to the epiphyseal line. (N. B.—I am aware that Colles in his original paper placed it at 1½ inches from the margin.) If none of the 6 screws involved the epiphysis, some of them must have been uselessly distributed over the upper fragment. There is no record of their being removed, although the lower epiphysis is the one at which growth mainly takes place. The ulna was not plated and deformity would appear to be inevitable. Perhaps, however, there is an explanation for the lack of deformity in these cases, namely, the extraordinary powers of resistance in Colonel Hallilay's young patients.

From the notes of the case of Ashraf Bibi, aged 7, we learn that on 13th October, 1923, two plates and eleven screws were applied to her fracture. About 2 years later skiagrams 3 and 4 are taken, one showing lateral and the other antero-posterior views. Not only do we find that there is an absence of rarefaction about the screws, but that 1 plate and 5 screws have been totally absorbed.

Colonel Hallilay has kindly recommended to me the perusal of a student's textbook of surgery. I am not ungrateful and would recommend in return Wilson and Cochrane's *Fractures and Dislocation.* (It and Scudder's new edition are the latest works on fractures.)

A careful perusal of the first chapter of the former, entitled "Principles of Treatment," will I hope enable him to exercise a better balanced judgment. On page 8 he will find the authors have ".....a decided preference for plaster of Paris as a splinting material" and on page 7 that for reduction "anæsthesia is practically always indicated."

I heartily endorse his last remark about methods being really up-to-date before venturing to criticise, etc., but it applies more strongly if we add ridicule to our criticism.

Colonel Hallilay himself uses plates and screws demonstrated by Hey Groves to be mechanically unsound as far back as 1913, (*British Journal of Surgery*, January 1914).

Plaster of Paris and anæsthesia are advocated in the three most recent works on fractures and by a surgeon of repute at the last meeting of the British Medical Association.

The more extended use of plaster of Paris at the present time is largely due to the advocacy of surgeons who have specialised in the treatment of fractures. These surgeons have devoted their professional careers to the study of fractures and have had infinitely better opportunities of observing and judging results of all methods of treatment than either Colonel Hallilay or myself can ever hope to have.

In conclusion, my letter was mainly a protest against the tone of Colonel Hallilay's article. It has obviously failed and I do not propose to continue the correspondence further, but leave it to your readers to draw their own conclusions.—Yours, etc.,

A. H. PROCTOR, *Lt.-Col.*, I.M.S.

CALCUTTA,
3rd February, 1927.

THE *FIELD* DISTEMPER FUND.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR.—We venture to request once more the hospitality of your valuable columns in order to inform the public of the progress of that research into the causes and prevention of distemper which has only been rendered possible by their constant munificence and their patient confidence in our efforts for so long a period. In our special buildings at Mill Hill, the continuous industry of the scientific workers of the Medical Research Council has produced results which have never been achieved before. A summary of our scientific report will shortly be sent you. Very briefly we will attempt to condense it in simple language into a reasonable space:—(1) Our investigators have confirmed that a filter-passing ultra-microscopic virus is the primary cause of distemper, and they have described the symptoms of the disease itself as distinguished from its many secondary maladies. (2) They have, by inoculation, rendered several of our puppies so far immune from the perils of distemper that a slight and temporary rise in temperature was the sole result of subsequent infection with the disease. (3) This means that on the lines along which they are working it is expected that a method will be evolved which will be capable of conferring upon dogs a lasting immunity from distemper.

It is necessary to explain further (*a*) why this immunity cannot be at once enjoyed by every dog, and (*b*) what may well be the last big step necessary for producing a safeguard which will not only be useful under practical conditions but easily procurable in all parts of the world where dogs are suffering from distemper.

The only process which can at present be employed involves the use of crude materials of uncertain and inconstant strength and quality. It is therefore completely unfitted for use by anyone except the skilled biologist working under the specially controlled conditions which we have created. There are several ways by which a more practical method may be developed and standardised; but an essential preliminary is the successful cultivation of the distemper-virus outside and apart from the body of an animal, to provide a more

Malaria

"It is most important in malaria cases that the diet should consist largely of milk. It is a remedy which possesses great value and one without which the child is not having a fair chance." *(Birch's Medical Treatment of Children in India, 6th Edition, p.238.)*

Malarial subjects find difficulty in digesting cow's milk but none in absorbing Glaxo, for the Glaxo process changes the physical character of the protein, so that on treatment with the gastric juices it forms a light flocculent precipitate, exactly comparable with that of breast milk.

Give your patients a "fair chance" by prescribing Glaxo.

abundant and satisfactory vaccine of constant quality and measurable strength. Thousands of experiments in this direction with filter-passing viruses of one kind or another are going on all over the world. It may take another month, another year, or more, to achieve our purpose; no one can tell. But we have done enough already to be able confidently to predict success, if we continue to receive support.

What that success will mean, both to dogs and to the human race, the communications you have published in a previous issue have sufficiently explained. But it is more than a year since we trespassed on your courtesy for space, and we do so now without any sensational appeal for urgent or excessive pecuniary aid. That aid has steadily been forthcoming, week by week, until we have reached within five thousand pounds of the £25,000 estimated as the total necessary for the completion of our work. Our old friends continue to stand by us. It is only therefore to bring our work to the notice of those who may still be unaware of it that we send you this letter; for we believe that no Englishman who owns or ever owned a dog will wish to stand outside the only movement that has ever given a certain prospect of mitigating the intolerable trouble of distemper. Supporters of our Fund should communicate with its Organising Secretary at Windsor House, Bream's Buildings, London, E.C.4. They will appreciate the fact that owing to our co-operation with the Medical Research Council, every ten shillings sent us immediately attains the value of a sovereign.

We desire publicly to express our thanks to all our helpers in the past year, to the Princes of India and our sporting fellow-countrymen in that great division of our Empire, to correspondents from all parts of the world who have read our previous statements in your columns, and more especially to the devoted, skilful, and indomitable labour of the scientific men to whom are due the real achievements rendered possible by the generosity of your readers.—Yours, etc,

PORTLAND,
(*President of the* Field *Distemper Council*).
BUCCLEUCH,
(*Vice-President*).
THEODORE A. COOK,
(*Hon. Secretary*).

THE TREATMENT OF CHOLERA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—With reference to the article by Dr. S. Rajaram Bharati, L.M.P. in the December 1926 number of the *Indian Medical Gazette*, in which the author attempts to contrast the efficacy of Mist. Pro. Diarrhœa with Tomb's essential oils mixture, in the first place, I would remark that the number of cases quoted is by no means large enough to form the basis of any conclusions. Secondly, in Treatment *A*, he combines the Mist. Pro. Diarrhœa with an anti-cholera pill; whilst in Treatment *B*, together with the essential oils mixture, potassium permanganate pills are used. Obviously, if any strict comparison is to be made, the two mixtures should have been given alone, or the same adjuvant should have been used in both groups of cases.

In this Presidency we have had a very large experience of treatment of cholera with Mist. Pro. Diarrhœa, and the results obtained, far from being disappointing, show that in this mixture we have a very valuable method of combating the disease. It is only to draw attention to this fact that I would ask space for this letter in your next number.—Yours, etc.,

A. J. H. RUSSELL, C.B.E., M.D., D.P.H.,
Lt.-Col., I.M.S.,
Director of Public Health.

MADRAS,
6th January 1927.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Major-General W. H. Ogilvie, C.B., C.M.G., K.H.P., Indian Medical Service, to be Director of Medical Services in India, *vice* Major-General O. L. Robinson, C.B., C.M.G., K.H.P., British Service, vacated. Dated 3rd January 1927.

The services of Lieutenant-Colonel W. W. Jeudwine, C.M.G., M.D., I.M.S., Civil Surgeon, Simla West, at present on combined leave in England, are re-placed at the disposal of the Government of the Punjab, with effect from the 1st December 1926.

Lieutenant-Colonel A. D. Stewart, I.M.S., Director of Public Health Laboratory and Professor of Public Health Laboratory-Practice, School of Tropical Medicine and Hygiene, Calcutta, is appointed to be Professor of Hygiene at the said School, with effect from the date on which he takes over charge of the appointment.

Lieutenant-Colonel N. M. Wilson, O.B.E., I.M.S., Officiating Civil Surgeon, Simla West, is confirmed in that appointment, with effect from the 1st December 1926.

Major H. Hingston, M.D., I.M.S., is appointed to act as Second Resident Surgeon, Presidency General Hospital, *vice* Captain S. A. McSwiney, M.B., F.R.C.S.I., I.M.S., granted leave.

The services of Major H. S. Anand, I.M.S., are placed temporarily at the disposal of the Government of Burma with effect from the date on which he assumes charge of his civil duties.

Subject to His Majesty's approval, the undermentioned officers have been appointed permanently to the Indian Medical Service as Lieutenants by the Right Hon'ble the Secretary of State for India. Their Commissions will bear dates as specified:—

M. K. Kelavkar, M.B.E., M.B. (Captain, I.M.S.—T.C.) Previous mobilized service as a temporary officer in the Indian Medical Service from 18th August 1919 to 25th August 1926 counts for pay, pension and promotion. Dated 26th August 1926.

G. S. Gill, M.B. (Captain I.M.S.—T.C.). Previous mobilized service as a temporary officer in the Indian Medical Service from 20th June 1923 to 25th August 1926 counts for pay, pension and promotion. Dated 26th August 1926.

Ranjit Sen, M.B. (Captain I.M.S.—T.C.). Previous mobilized service as a temporary officer in the Indian Medical Service from 7th February 1917 to 26th September 1926 counts for pay, pension and promotion. Dated 27th September 1926.

LEAVE.

Colonel K. V. Kukday, C.I.E., I.M.S., Inspector-General of Civil Hospitals, Central Provinces, is granted leave, preparatory to retirement, for 8 months on average pay with effect from the 15th January 1927.

Major E. W. O'G. Kirwan, F.R.C.S.I., I.M.S., officiating Civil Surgeon, Mymensingh, is granted leave on average pay for four months, with effect from the afternoon of the 22nd December 1926.

This department notification No. 3404 Medl., dated the 21st December 1926, is hereby cancelled.

Captain S. A. McSwiney, M.B., F.R.C.S.I., I.M.S., Second Resident Surgeon, Presidency General Hospital, is allowed leave for one year with effect from the 25th January 1927 or any subsequent date on which he avails himself of the leave.

PROMOTIONS.

Colonel to be Major-General.

Andrew Armstrong Gibbs, K.H.P., *vice* Major-General Walter Holland Ogilvie, C.B., C.M.G., M.B., K.H.P., appointed Director of Medical Services in India. Dated 3rd January 1927.

The promotion of Major J. B. de W. Molony, O.B.E., M.B., F.R.C.S.E., I.M.S., notified in Army Department Notification No. 1128, dated the 3rd September 1926, is antedated from the 6th August 1926 to 6th February 1926.

Lieutenants to be Captains.

M. K. Kelavkar, M.B.E., M.B. Dated 26th August 1926, but to rank from 18th August 1920.

G. S. Gill, M.B. Dated 26th August 1926, but to rank from 20th June 1926.

Ranjit Sen, M.B. Dated 27th September 1926, but to rank from 7th February 1918.

Garrett Joseph Joyce, M.B. Dated 22nd December 1926.

James Scott Riddle, M.B. Dated 8th January 1927.

Gilbert Marshall Irvine, M.B. Dated 1st August 1926.

Temporary Lieutenants to be temporary Captains.

Asa Nand Narang, M.B. Dated 1st December 1926.

Ram Labhaya, M.B. Dated 12th December 1926.

RETIREMENTS.

Lieutenant-Colonel E. F. G. Tucker, I.M.S., with effect from the 24th October 1926.

Lieutenant-Colonel D. W. Sutherland, C.I.E., I.M.S., with effect from the 18th December 1926.

NOTES.

THE ALVARENGA PRIZE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Senor Alvarenga, and amounting to about Three Hundred Dollars, will be made on July 14, 1927, provided that an essay deemed by the Committee of Award to be worthy of the Prize shall have been offered.

Essays intended for competition may be upon any subject in Medicine, but cannot have been published. The essay should represent an addition to the knowledge and understanding of the subject based either upon original or literary research. They must be typewritten, and in English acceptable for publication without necessity for editing by the Committee. Any illustrations should be appropriate and correctly annotated with the text. Essays must be received by the Secretary of the College on or before May 1, 1927.

Each essay must be sent without signature, but must be plainly marked with a motto and be accompanied by a sealed envelope having on its outside the motto of the paper and within the name and address of the author.

It is a condition of competition that the successful essay or a copy of it shall remain in possession of the College; other essays will be returned upon application within three months after the award.

The Alvarenga Prize for 1926 has been awarded to Drs. P. S. Pelouze and F. S. Schofield for their Essay entitled "The Gonophage."

LONDON MEDICAL EXHIBITION 1926. CENTRAL HALL, WESTMINSTER, LONDON, ENGLAND, OCTOBER 4 TO 8.

Burroughs, Wellcome and Co.'s Exhibit.

MOST medical men, whatever the field of their labours, found something of especial interest in the wide range of products exhibited by Burroughs, Wellcome & Co. Grouped alongside photographs of the highly-magnified organisms responsible for certain diseases were the appropriate medicaments for dealing with the disorders, together with a selection of 'Soloid' microscopic stains that appealed to those interested in the practical side of bacteriology.

A full range of 'Tabloid' animal substances was shown, including 'Tabloid' thyroid gland, 'Tabloid' mixed glands and 'Tabloid' parathyroid gland. In special racks were shown the various stages in the production of 'Tabloid' animal substances, from the fresh raw material to the finished compressed products. 'Welcome' Brand insulin and 'Tabloid' Brand hypodermic insulin (the only British insulin issued as a compressed product, remind us of the pioneer rôle played by Burroughs, Wellcome & Co. in the early days of insulin treatment, and of their subsequent researches which have materially lowered the price and increased the supply of this valuable medicament.

Worthy of special attention were the 'Wellcome' Brand bismuth salts, for which an exceptionally high standard of purity and physical and chemical uniformity is claimed, and 'Wellcome' Brand sodium salicylate, which dissolves easily and is physiologically pure. These preparations are characteristic of the fine chemicals manufactured by this well-known house.

Potential additions to the medical man's armamentarium were exhibited in 'Avenyl' (a mercurial preparation soluble in hydnocarpus oil) and 'Neostam.' The former has been evolved for dealing with cases of syphilis complicated with leprosy. 'Neostam' stibamine glucoside has been found of service in kala-azar, and in other conditions where tartar emetic has hitherto been used.

Of general interest was the display of 'Wellcome' Brand vaccines, sera, tuberculins and diagnostic products, prepared at the Wellcome Physiological Research Laboratories and distributed by Burroughs, Wellcome & Co.

REGULIN FLAKES.

A VERY interesting and palatable preparation is Regulin Flakes for the treatment of habitual constipation, prepared by the Regulin Syndicate, 14, Philpot Lane, London, E. C. 3. Habitual constipation is especially prevalent in the tropics, and especially so amongst women, whilst treatment of the condition by violent aperients only tends in the long run to aggravate it.

Regulin Flakes are a combination of agar-agar with a tasteless preparation of cascara; the former having a purely mechanical and water-absorbing evacuant action in the intestine, whilst the latter increases peristalsis without causing colic. The preparation is practically tasteless and can be taken mixed with food or simply stirred into water, tea, or coffee. The dose for patients with habitual constipation is from one teaspoonful to one tablespoonful (according to requirements) taken three times a day until the bowels have become regular.

This preparation is one of the most elegant that we have seen, and reports in the *Lancet* and *British Medical Journal* speak well of it. The sole agents for India, Burma and Ceylon are Messrs. Mangalik and Co., Seva Sadan, Meerut City, United Provinces, India.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c/o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

THE TREATMENT OF PUERPERAL ECLAMPSIA, WITH NOTES ON 220 CASES OF PUERPERAL ECLAMPSIA TREATED AT THE GOVERNMENT HOSPITAL FOR WOMEN AND CHILDREN, MADRAS, DURING THE YEARS JANUARY 1922 TO JULY 1926.*

By C. A. F. HINGSTON, C.I.E., O.B.E.,
LIEUT.-COL., I.M.S.,
and
A. LAKSHMANASWAMI MUDALIAR, B.A., M.D.
Madras Government Maternity Hospital.

IN a paper contributed by us to the *Indian Medical Gazette* in 1922 we submitted an analysis of 450 cases of eclampsia treated at the Madras Maternity Hospital between the years 1908 and 1922, and then touched therein on some factors which we thought were of primary importance in the treatment of the disease.

Since the publication of this paper, we have had under our treatment a large number of cases, wherein we had the advantage of not only putting into practice the principles we had enunciated, but also closely following each one of these cases. It is not often that one can publish an analysis of over 200 cases of eclampsia wherein one definite line of treatment was followed and the same persons practically were privileged to observe and treat the condition. Our results must therefore be interesting from this point of view if from no other, and we feel no apology will be required of us in submitting our experiences and our results to this Congress.

During the period under review, 12,733 women were confined at the Government Hospital for Women and Children, of whom 3,511 were primiparæ and 9,222 multiparæ, and there were 220 cases of eclampsia, giving a rate of incidence of 1.73 per cent. This shows a very high rate indeed, the only other rate which exceeds this being that of Lichtenstein, whose rate was 2.68 per cent. Of the 220 cases, 139 were primiparæ and 81 multiparæ, so that the percentage of the primiparæ was 63.18 and among multiparæ 36.82. It should also be noted that the incidence of this disease among primiparæ was 3.96 per cent. and among multiparæ 0.88 per cent., thus showing that it is 4.5 times as great among primiparæ as among multiparæ.

Distribution according to age and number of pregnancy.—The youngest recorded was in a girl of 15 years, while the oldest was a 14th-para aged 45 years. Eclampsia occurs most frequently in primiparæ and decreases with subsequent pregnancies. Thus there were 139 cases in primiparæ, 24 in 2nd pregnancies, 22 in 3rd pregnancies, 11 in 4th pregnancies and 8 in 5th pregnancies.

Clinical features.—Eclampsia occurs almost always in the second half of pregnancy, the earliest period at which it occurred in this series being the 6th month. It generally tends to increase in frequency in the later months and is most frequent at term. An observation of some interest is the fact that it tends to occur earlier in the course of pregnancy in multiparæ than in primiparæ. Thus, while it occurred before full term in 20 per cent. of the cases in primiparæ, in over 57 per cent. of the cases in multiparæ the fits came on before term. The latest period when the disease occurred was the 29th day after confinement. The disease is relatively more common in twin pregnancies, there having been ten cases among twin cases giving a rate of incidence of 4.63 per cent., while the percentage of twin cases to total number of cases treated was 1.69 per cent.

The condition is commonly seen in well built, plethoric individuals. Œdema was marked in nearly 50 per cent. of the cases. In cases where a fairly cogent history could be obtained, the chief prodromal symptoms complained of were headache, epigastric pain and visual disturbances. Seventy out of 220 cases were admitted in an unconscious condition. Diminution in the quantity of urine passed was noted in over 70 per cent. of the cases. Only one patient in her fourth pregnancy gave a history of eclampsia in her first and third pregnancies.

Blood pressure.—This, in our experience, is the most important factor to be noted in cases of eclampsia. The blood pressure is generally well over 140 mm. in cases of eclampsia, and usually varies between 160 and 170 mm. The highest blood pressure noted was 220 mm., while the lowest on record was 55 mm. after an injection of veratrone. We have noticed that a high blood pressure generally predisposes to a larger number of fits and to a greater degree of coma. Thus, in over 80 per cent. of the cases where more than 10 fits occurred, the blood pressure varied between 170 and 220 mm. This has an important bearing on the treatment as will be noticed later.

Albuminuria.—Albuminuria was not a constant feature in these cases. Thus it was present in 89 per cent. of the cases where the urine was examined soon after the fits. The amount of albumin present is not proportionate to the severity of the case and in most cases the condition clears up in a few days.

The temperature is usually normal at the time of occurrence of the fits, but later shows

* A paper read at the *Indian Science Congress*, Lahore, in January, 1927.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

a tendency to rise in some cases. Occasionally hyperpyrexia may set in. In 17 cases in this series the temperature rose to 104°F. and over within the first 24 hours. Later in the course of the disease the fever may be due to complications in the lungs or to puerperal sepsis. The convulsions are the chief clinical symptom of the disease. In over 90 per cent. of the cases the patients were admitted with a history of having had fits at home, the number of fits varying from 1 or 2 to 20 or 30. The fits are more common during labour, less so during pregnancy and much less during the puerperium. It was noticed that 46.8 per cent. of the cases occurred during labour, 27.7 per cent. were ante-partum and 25.5 per cent. post-partum. The largest number of fits occurring in any single individual was 72 and it is interesting to note that the patient recovered. The degree of coma varies with the number of fits, but we have noticed cases where the coma was deep even with a few fits, and one case in which after a single fit the patient never recovered from deep coma.

The chief complications noticed were œdema of the lungs, broncho-pneumonia, deglutition pneumonia, failure of the heart, and puerperal insanity. Puerperal sepsis is perhaps more likely in cases of eclampsia.

Treatment.—The treatment of puerperal eclampsia may be dealt under the four headings.

(1) Treatment during a fit.
(2) Prevention of fits.
(3) Treatment of labour.
(4) Treatment of complications.

(1) *Treatment during a fit.*—During a fit, the mouth gag is inserted, care being taken to see that it is slipped in between the molars, as otherwise cases have occurred when an excitable nurse or attendant has forced the gag from in front causing dislocation of the incisors. The patient should be turned to one side and kept in the recumbent posture either on an eclamptic board or on a protected cot; all tight fitting garments and jewels should be loosened or removed and the respiration watched, the tongue being prevented from slipping back. Excepting that care should be taken to prevent the patient from injuring herself during the convulsions, it is unnecessary to restrain her forcibly.

(2) *Prevention of fits.*—This is one of the most important of the problems in the treatment of the disease. We do not know definitely what is the causative factor in eclampsia and our treatment must be in the main empirical. We are convinced that the control of fits is essential and that the most important factor to be reckoned with is the high blood pressure. Our treatment then is directed towards the reduction of the high blood pressure. At first we attempted to do this by venesection. The median basilic vein or cephalic vein was opened and from 12 to 20 ounces of blood were let out, so that the blood pressure was reduced to 120 mm. or less. At one stage we used to transfuse normal saline into the veins with the hope that thereby the toxins in the blood would be diluted.

We hold that these measures are unnecessary and undesirable. Since 1922, we have used veratrone, the active principle of *Veratrum viride,* to reduce the blood pressure; 1 c.c. of veratrone (P. D. and Co.) is given subcutaneously if the blood pressure is above 140 mm., and ½ c.c. if it is below. This produces a sharp fall in the blood pressure in 15 to 30 minutes and the blood pressure is kept down for varying periods afterwards. In most cases two injections at an interval of 2 to 3 hours sufficed. We have however given as much as 6 c.c. of veratrone in 24 hours with no bad results. In cases where a high blood pressure persists in spite of repeated injections of veratrone, we have performed venesection with good result. This method of treatment was adopted in the case reported above where the patient had 72 fits. The injection of veratrone produces a rapid and considerable fall in blood pressure and a corresponding fall in the pulse rate. Occasionally the blood pressure falls very suddenly and alarming signs of collapse occur, but these are rapidly overcome if the patient is given an injection of strychnine, and later saline and glucose per rectum.

We have used veratrone very largely as a prophylactic in cases of threatening eclampsia (albuminuria with persistent high blood pressure) with uniformly good results. The injection of veratrone occasionally causes severe vomiting, the patient sweats freely and feels a sinking sensation in the epigastrium. The symptoms however do not persist for long and in a couple of hours, the patient perhaps dozes off to sleep.

Besides the injection of veratrone, morphia is given to check the fits. We start with an initial dose of ¼ to ⅓ grain and repeat it at intervals of 2 to 3 hours if fits persist. Since commencing the use of veratrone we have noticed that it is not necessary to use morphia in such large doses, the maximum we have used being 1 grain in 24 hours.

Care should be taken to see that the patient is kept quiet in a darkened room, and that she is disturbed as little as possible, particularly when she is at all restless or mentally excitable. Under such circumstances it is wise to give an injection of morphia, and as soon as she is under its effects to proceed with the examination, to draw off the urine or to give her an enema.

When the patient is quiet she is given a large soap and warm water enema which is

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

followed by sodium bicarbonate bowel washes (1 drachm to 1 pint) every 4 hours.

We have given up the idea of gastric lavage, which at one time was extensively practised in this hospital. It has not in the least interfered with the recovery of the patient, but on the contrary we are convinced that lung complications occur much less frequently without it. Thus while such complications occurred in more than a third of the cases in the days of gastric lavage, our figures show that they occurred in less than 10 per cent. of the cases at present. If the patient is conscious she is given a saline purge, an ounce of magnesium or sodium sulphate.

We hold that no food of any description should be given for at least 12 hours after the woman ceases to have any fits and regains consciousness. Eclamptics stand starvation quite well and any attempt at forcing food, even if it be milk, increases the chances of fits and might increase the tendency to deglutition pneumonia. When the patient is conscious she is given milk and barley water.

(3) *Treatment of labour.*—We hold that *accouchement forcé* should never be adopted in cases of eclampsia and we are definitely of opinion that nothing is to be gained by precipitating labour whatever may be the method employed. Our teaching is to leave the woman alone, so far as labour is concerned but to terminate the second stage of labour earlier without waiting for signs of fœtal or maternal distress. Thus we deliver the woman if the os is nearly fully dilated and the membranes ruptured. This we do in the interests of both mother and child, the mother because the strain on the heart may be severe and a certain amount of hæmorrhage consequent on delivery would relieve it and lessen the blood pressure, the child because we have noted that the longer the fœtus is *in utero* after rupture of membranes, the greater is the degree of oligopnœa or asphyxia.

Of the 220 cases referred to, 211 were delivered in the hospital, of whom 131 were delivered by natural powers and 20 by artificial aid. The maternal mortality among the natural deliveries was 5.34 per cent., while among the aided labours there was a mortality of 16.25 per cent.

(4) *Treatment of complications.*—The best method of treating complications is to prevent them, and many of the complications of eclampsia can be prevented. Careful and intelligent nursing are essential. The patient should be kept on each side alternately, mucus cleared from the throat, care taken that the head is low in cases of vomiting and care in feeding. All these will reduce the risks of lung complications. For œdema of the lungs, besides reducing the blood pressure, injections of atropine, adrenalin and strychnine are useful.

Oxygen inhalations may be given, and where broncho-pneumonia has supervened the usual treatment for this condition should be adopted. The condition of the heart should be carefully noted and cardiac stimulants given when necessary.

Scrupulous care should be observed in all vaginal manipulations as sepsis is more prone to occur in eclamptics.

For hyperpyrexia, iced enemas and hydrotherapy to the extremities would be of value.

In cases of cerebral irritability and mania, large doses of bromides, occasionally combined with chloral or injections of hyoscine have been given.

Prognosis.—The prognosis depends on several factors.

1. The frequency of the fits.
2. The degree of coma.
3. Temperature.
4. Pulse.
5. The extent of albuminuria.
6. Lung complications.
7. Nature of delivery.
8. The time of admission for treatment.
9. Whether the fits occurred *ante-partum, intra-partum* or *post-partum.*
10. High blood pressure.

A large number of fits (over 12), deep coma, a temperature above 104°F, rapid pulse, severe albuminuria, broncho-pneumonia and œdema of the lungs, artificial delivery if hurried, are all factors leading to a bad prognosis. The later the patient comes under treatment after the first fit, the worse the prognosis. A persistently high blood pressure is of bad prognostic significance. The prognosis is more favourable in post-partum eclampsia than in ante-partum and is worst in intra-partum cases.

Results.—Of the 220 cases treated during this period, 22 ended fatally, giving a gross mortality of 10 per cent. Of these, 4 cases were admitted in a moribund condition and died within 4 hours after admission. Moreover, in judging the results of the treatment referred to above, it is only fair that cases treated by other methods should be excluded. There were 5 such cases with 2 deaths. Excluding the moribund cases and the cases treated along other lines, we get a corrected maternal mortality rate of 7.58 per cent. We are of opinion that if the treatment we have adopted is carried out in all its details, the mortality from puerperal eclampsia would not exceed 6 to 8 per cent. The figures are sufficiently large and the period covered extensive enough to test the value of the treatment adopted.

Infantile Mortality.—221 children were delivered, of whom 142 were born alive, 63 still, and 16 macerated. The percentage of live births was 64.28. Of the 79 cases of still

THE TREATMENT OF PUERPERAL SEPSIS, WITH SOME NOTES ON THE BACTERIOLOGY OF PUERPERAL FEVER.*

By C. A. F. HINGSTON, C.I.E., O.B.E.,
LIEUT.-COL., I.M.S.,
and
A. LAKSHMANASWAMI MUDALIAR, B.A., M.D.,
Madras Government Maternity Hospital.

PUERPERAL sepsis is still one of the most serious complications in the puerperium and stands perhaps foremost among the causes of maternal mortality following childbirth. Despite all the improvements in bacteriological technique and the knowledge gained from a close study of the bacteriology of puerperal fever, it must be stated that there has been no appreciable difference in the incidence of this disease within the past twenty years even in Great Britain. Statistics show that. In this country the incidence of the disease is very much greater. In Southern India maternal mortality from sepsis is at least 6 to 8 times as great as it is in England and Wales, and in the city of Madras the returns show that 1 out of every 60 mothers dies from puerperal sepsis. The problem then of prevention and cure of this serious complication is one that deserves the close attention of all obstetricians in this country more than anywhere else, and it is to focus that attention and to stimulate a discussion that we have ventured to submit this paper to the Congress. At the Government Hospital for Women and Children in Madras about 3,000 women are confined every year, while a large number of women confined outside are admitted suffering from puerperal sepsis of varying severity. The scope then for a close study of this disease as it manifests itself under local conditions has been considerable, and while we do not lay any claim to any new line of treatment, we think it will not be out of place to put on record our experience in regard to the treatment of this disease.

During the last twenty years it has been the practice in this hospital to segregate all women who are in labour but who have been examined outside to a separate wing, where the patients are delivered in a separate labour ward and accommodated in the puerperal wards adjoining. No patient is refused admission and all women confined outside and brought in with or without signs of puerperal sepsis are likewise kept separate in the septic block. This has to a very large extent reduced the chances of infection in the hospital.

Prophylaxis.—This undoubtedly is of the greatest importance and naturally commands

* Being a paper read at the *Indian Science Congress*, Lahore, in January 1927.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the greatest attention in a training institution such as ours. Perhaps no factor is of greater importance than that of the ante-natal care of the mother. Our experience is that sepsis is very much rarer among the *batta* women who are kept under our personal observation during the last two or three months of pregnancy and given a daily dole of two annas. These women are carefully looked after and attended to at an early stage.

It needs no emphasis to say that the most potent factor in the production of sepsis is the attendant, and while we are not prepared to deny the possibilities of intrinsic infection, it may safely be stated that extrinsic infection or possibilities of it should never be ruled out so long as any sort of manual interference has been attempted. Strict antiseptic precautions are required whether gloves are used or not, and vaginal examinations should be made only when considered inevitable. The proper cleansing of labia and perineum and care in vaginal examination and the introduction of the finger by sight after well separating the labia are of importance.

In normal labour a vaginal douche is never given. In cases of prolonged labour, when the cervix is not fully dilated and the membranes have ruptured, and in cases where the woman has been handled outside and the vagina badly bruised or where a purulent vaginal discharge is present, a hot vaginal douche with lysol (1 drm. to the pint) is given.

Our experience is that there are greater risks of sepsis in the application of forceps than in most of the other obstetric operations, excepting the manual removal of placenta. We have rarely met with severe sepsis in cases of version even when performed in cases of neglected transverse presentation. In particular where the forceps are applied in occipito-posterior or mento-posterior presentations, or in minor degrees of contracted pelvis or where the head is high up, in cases where the cervix is rigid or the anterior lip is prolapsed, the cervical and vaginal lacerations that are almost inevitable are fruitful causes of sepsis. We have practically given up the operation of high forceps, and prefer version and extraction, provided there are no contra-indications. It is of great importance to repair all tears wherever possible and we found the application of Tr. Benzoin Co. efficient in arresting the oozing and preventing sepsis in all cases of vaginal and cervical lacerations.

Two conditions especially predispose to puerperal sepsis, post-partum hæmorrhage, and retention of membranes, blood clots or bits of placenta. Every care should be taken to prevent the latter, but we are definitely against any intra-uterine manipulation to remove membranes or small bits of placenta immediately after delivery.

Treatment.—The treatment of puerperal sepsis depends very much on the condition of the patient when first seen and whether the patient is suffering from a localised infection of the generative tract or from a generalised infection. If the temperature rises above 100°F. during the puerperium, an immediate investigation should be made to find out the cause, and in the absence of any definite causative factor, the case should be deemed to be one of puerperal sepsis. In this country some of the factors which may give rise to fever during the puerperium are malaria, dysentery, pneumonia, kala-azar, tuberculosis, and intestinal worms. When however none of these causes are present, a careful examination of the patient is needed. The pulse and temperature and the general condition of the patient is noted. The height of the uterus should be noted and whether it is well contracted or flabby, painful and tender. The lochia should be observed, its colour, smell, method of staining, its character and quantity, particular care being taken to note the presence or absence of clots, fragments of placenta and membranes. The perineum should be examined with a view to find out if there have been any lacerations, or if sutured whether the sutures are taking and the perineum healthy. We generally examine the patient on the table in order to note the condition of the cervix and vagina. At the same time cervical and uterine swabs are taken for bacteriological examination. A hot vaginal douche is given, any ulcers present in the vagina or cervix are touched with a fairly strong antiseptic such as medical izal, tincture of iodine, tinctura benzoinæ co., or a saturated solution of picric acid, and if the perineal stitches are unhealthy they are removed and the perineum laid bare to promote free drainage.

The vaginal douche.—In cases of sapræmia hot vaginal douches are given every four hours if necessary, the solutions used being lysol (1 in 160), iodine (1 in 80), eusol, and saline. Where the lochia are very foul smelling, iodine douches are preferred. The vaginal douche helps to clean the parts, favours free drainage and provokes uterine contractions.

In cases where there is extensive sloughing of the vaginal walls and cervix—what is termed here the 'cesspool vagina'—continuous irrigation with a mild antiseptic is very efficient. Weak lysol or saline is generally used and the douche is given continuously except for an interval of 2 hours by day and 4 hours by night. In case the perineum is œdematous or badly ulcerated hot boracic compresses are advisable.

The Uterine Douche.—The place of the uterine douche in the treatment of puerperal

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

sepsis is a debatable point. We have for some years past considerably limited the scope of the intra-uterine douche. With all precautions, it is not free from risks, and in most cases its value is doubtful. In cases of pyometria no doubt it helps to drain the uterus and there is a sharp fall in the temperature and marked improvement in the general condition of the patient. The mechanical use of the intra-uterine douche in all cases of sepsis or even in cases of pyrexia during the puerperium cannot be too strongly condemned It is by such methods that a mild case is converted into a severe one. Since discontinuance of the frequent use of the uterine douche we have noticed that the period of pyrexia in sapræmic cases is very much less and that fewer cases develop into the severe forms of sepsis.

Curettage and Ecouvillonage.—We have found that even in cases where the uterus is filled with decomposing lochia, drainage with the help of a Budin's tube is sufficient. This may be repeated on alternate days or even daily if necessary and has the advantage over the uterine douche that the patient does not suffer from shock or hyperpyrexia. In cases where it is suspected that bits of placenta or membranes or disintegrating blood clots are left behind in the uterus, it is advisable to remove them by digital evacuation of the uterus. With the patient under chloroform it is often possible to completely explore the uterus by careful bimanual manipulation.

The next method adopted in this hospital is a modified écouvillonage. Instead of using the brush, a rough piece of sterilized gauze is wound round an intra-uterine forceps and the whole of the inside of the cavity is swabbed round. This is done three or four times till all the debris is removed. It may be done after digital exploration and has proved very useful.

We are definitely of opinion that the curette is not a safe instrument to be used in the puerperium. It is ineffective, lays open fresh channels of infection, causes severe hæmorrhage at times, may lead to risks of perforation and generalised infection. Since the practical abandonment of the curette we have noticed a distinct diminution in the number of severe cases of sepsis and a more rapid recovery in cases treated without curettage. We must state that we have frequently come across cases where curettage has been done for uterine sepsis with the result that the condition has become much worse and septicæmia has supervened. Even in cases where curettage is supposed to have been beneficial, we are inclined to the belief that the cases would have improved under a more conservative line of treatment. We must add however that the use of the curette in infection occurring as a result of abortion in the early months of pregnancy is not only justifiable but is attended with very favourable results.

Postural Treatment.—A good method of favouring drainage is to raise the head of the bed or put the woman in Fowler's position. This generally helps to drain the uterus and vagina and tends to limit the possibilities of the spread of infection into the peritoneum. It may be stated here that distension of the bladder leads to the retardation of the free flow of lochia and thus favours a lochiometria or pyometria. In all cases of instrumental delivery care should be taken to see that the bladder is emptied in time, as otherwise the uterus may be pressed upon and get displaced backwards.

In cases of sub-involution ecbolics are needed, a mixture of the liquid extract of ergot with quinine being commonly given. Injections of pituitrin given daily or twice a day are also of considerable value. Hot vaginal douches should be given, at least twice a day.

Operative measures.—The question of operative treatment in cases of puerperal infection has been much discussed of late. The operations suggested are hysterectomy, laparotomy, salpingectomy and oophorectomy, posterior colpotomy, ligature or excision of the pelvic veins. We have not been in favour generally of the principle of operative treatment in cases of puerperal sepsis and the results obtained by those who advocate such methods of treatment have not been encouraging. We have limited the use of operative measures to definite indications. In cases where there is a definite swelling in Douglas's pouch which is fluctuating, the abscess may be drained by an incision into the posterior fornix. Even here it may be stated that in many cases of pelvic cellulitis the inflammation subsides with absolute rest in bed, hot vaginal douches, warm boric bowel washes, icthyol and glycerine (10 per cent.) tampons to the vagina. In a large proportion of cases the symptoms gradually subside an the exudate is almost completely absorbed in the course of a few weeks.

When the cellulitis goes on to suppuration, the abscess should be opened in the most favourable position for drainage. In many cases the abscess can best be opened by an incision along the iliac region parallel to Poupart's ligament.

In cases of infection of the Fallopian tube and ovary, we hold that a conservative line of treatment is indicated. We are not in favour of the removal of an acute pyosalpinx or ovarian abscess, and our experience is that it is very much better to decide the question after the acute stage has subsided. The treatment should in the meantime be directed to the peritoneal symptoms.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Opening and drainage of the abdominal cavity has been done in cases of puerperal peritonitis, but the results have not been satisfactory. In cases following abortion the operation is more successful.

Serum and Vaccine Therapy.—Antistreptococcic serum in cases of puerperal sepsis has not been found to be as useful as was first anticipated. In cases where the patient is already septicæmic, we have found it practically of no value. Used as a prophylactic, its value is undoubted. During last year the serum has been used in every case where the placenta had to be manually removed. Out of ten cases in which the serum was used, eight recovered. It may be stated that in seven of these cases the patient was confined at home and brought in 6 to 12 hours later in a condition of collapse with severe bruising of the vagina and cervix and the placenta adherent. Only one case died. The initial dose given was 20 c.c. and this was repeated daily. The temperature did not rise above 102°F. and the patient showed signs of mild sapræmia. We are of opinion that the result in these cases is not accidental and that antistreptococcic serum has its place as a prophylactic in puerperal sepsis. It may also be stated that in one of the fatal cases, uterine culture revealed the presence of *Bacillus coli* and perhaps this accounts for the fact that the serum was of no use. Stock vaccines (polyvalent) were used in a large number of cases with uniformly poor results. Autogenous vaccines have been tried in a few cases but owing to the delay in their preparation and the severity of the cases selected, it is not possible for us to speak of their value with any authority. We have recently isolated a large number of the different strains of streptococci, hæmolytic and non-hæmolytic, as well as other organisms occurring in cases of puerperal sepsis and a polyvalent vaccine has been prepared and is being given a trial. The results we shall watch with interest.

General treatment.—Careful nursing and a stimulating line of treatment should be followed in these cases. The diet should be light, liquid and easily digestible. Milk, arrowroot, Ovaltine, Benger's, are among the common foodstuffs given. Essence of chicken or Bovril is also used with advantage. Eggs, raw or as egg-flip, are usually well taken. Glucose and brandy or champagne may be given at intervals of two to three hours and are of value in cases of severe exhaustion.

For the pyrexia, hydrotherapy is generally practised. Strong antipyretics are to be deprecated. Injections of quinine have been given and occasionally proved beneficial. In cases of *B. coli* infection, hexamine in doses of 7 to 10 grains has been given intravenously, but the results have not been satisfactory.

In cases showing severe toxæmic symptoms saline solution has been used, either subcutaneously or *per rectum*.

Infection of the urinary tract is always a troublesome complication in septic cases. The use of the catheter during the puerperium should be discouraged as far as possible. Another cause of infection is tears of the clitoris and urethra, particularly in forceps delivery, where in attempting to save the perineum the forceps is carried too far forwards. The use of urinary antiseptics with the administration of large quantities of barley water generally suffices in most cases. Occasionally an ascending infection of the urinary tract results and the pyrexia may persist for a long period.

A complication of grave prognosis is the severe anæmia that occasionally develops in cases of puerperal sepsis. The anæmia though of the secondary variety progresses very rapidly and proves fatal. In such cases the patient fails to respond to any treatment and sinks gradually.

Sometimes cases of puerperal sepsis develop severe pains in the pelvic joints and are unable to move the limbs. This is accompanied at times with several neuralgic pains shooting down the thighs. Calcium therapy has been of some benefit in some cases but not in all, and the exact causation of this troublesome complication is not known.

Conclusion.—We have attempted to describe in a general way the treatment of puerperal sepsis as carried on at the Madras Government Hospital for Women and Children. During the past 10 years (1916-25) there were 26,531 deliveries. The total number of septic cases treated was 1,574 of which 282 cases were cases of puerperal septicæmia. There were 95 deaths from septicæmia and 7 from severe sapræmia. The mortality rate for septicæmia would thus be seen to be 34.68 per cent.

Our thanks are due to Dr. M. B. Prabhu, M.B., B.S., who was responsible for carrying out the actual treatment in these cases and whose careful notes and statistics were of great help to us in our work.

AN ANALYSIS OF RESULTS OF BACTERIOLOGICAL EXAMINATION OF UTERINE AND VAGINAL SWABS IN CASES OF PUERPERAL SEPSIS, THE NORMAL PUERPERIUM, AND PREGNANCY. (PERFORMED BY ASSISTANT SURGEON J. H. THEODORE, I.M.D., KING INSTITUTE, GUINDY.)

The study of streptococcal incidence in cases of puerperal fever was first undertaken. In this series a group of 120 cases were examined and streptococci were isolated from 77 or 64.2 per cent. of the cases examined. The relatively higher proportion of streptococcal

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

findings in relation to the severity of the cases may be seen from the following table:—

	Mild.	Severe.	Fatal.
Number of cases.	67	36	17
Number of cases associated with streptococcal infection ..	40	24	13
Proportion ..	59.7%	66.6%	76.4%

The total of 77 positive findings when further subdivided into the hæmolytic and non-hæmolytic varieties, group themselves as follows:—

	Mild.	Severe.	Fatal.	Total.
Hæmolytic variety ..	36	22	9	67
Proportion ..	90%	91.6%	69.2%	85.1%
Non-hæmolytic variety	4	2	4	10
Proportion ..	10%	8.4	30.8%	14.9%

The streptococci fell into one or other of Holman's groups.

The possibility of organisms other than streptococci being associated factors in puerperal fever was next considered. The next series of swabs from cases of puerperal fever were examined with a view to ascertaining their entire flora. The results obtained are tabulated as follows:—

	Streptococci.	*B. coli.*	Staphylococci.	Diphtheroids.	Other organisms.
Sapræmia ..	9	2	11	3	4
Septicæmia ..	6*	3	—	—	—

* Of these, streptococci were found in association with pneumococci and staphylococci in one case, and with *B. coli* in another.

The 29 cases of sapræmia, when analysed to shew the relation the isolated organisms bore to the severity of the case, indicate that streptococci and *B. coli* were associated with the more severe form of cases.

Sapræmia Cases, 29.

	Streptococci.	*B. coli.*	Staphylococci.	Diphtheroids.	Other organisms.
Mild ..	3	1	9	3	3
Severe ..	6	1	2	1	—
Fatal ..	—	—	—	—	—

Note.—Of the 3 streptococci findings two were from both uterine and vaginal and one from the vaginal swab only, the remainder isolated were for the most part from both uterine and vaginal swabs.

Septicæmia Cases, 9.

Mild ..	—	—	—	—	—
Severe ..	4	2	—	—	—
Fatal ..	2	1	—	—	—

The above table shows rather forcibly the predominance of streptococci and *B. coli* in the more severe and fatal forms of our cases, with a complete absence of the less virulent organisms which were so closely associated with the milder form of the disease.

Note.—The isolations in each instance in this series were from the uterine discharge and for the most part pure cultures. One of the fatal streptococcal infections gave in addition a growth of *B. coli.*

Vaginal Flora in 21 cases of full term. Pregnancy.

The results obtained in this group are as follows—

No growth.	Yeasts.	Diphtheroids.	Streptococci.	Staphylococci.	*B. vaginalis* and saprophytic bacteria.
7	6	4	1	1	2

The figures obtained in this table will be considered in the discussion of the endogenous nature of puerperal infections.

A series of 12 cases from which uterine and vaginal swabs were separately examined during a normal puerperium, gave the following results:

	No growth.	Yeasts.	Diphtheroids.	Streptococci.	Staphylococci.	Saprophytic bacteria.	Sarcinæ.
Uterine ..	9	—	3	—	—	—	—
Vaginal ..	—	3	10	2	2	2	2

In 8 of the vaginal findings more than one organism was found, diphtheroids being associated in two instances with each of the following: yeasts, staphylococci, sarcinæ and saprophytic bacteria.

CONCLUSIONS.

The above analysis shows that streptococci play a prominent part in the production of puerperal fever. The hæmolytic variety is more often associated with the serious cases, but its exact pathogenicity requires further investigation.

From an examination of the discharge—uterine and vaginal—in cases of puerperal fever, we noted that the following organisms were present in addition to streptococci in cases of sapræmia: *B. coli*, staphylococci,

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

diphtheroids, the *B. vaginalis* and other organisms. In septicæmia however the only organisms isolated were streptococci and *B. coli*.

We examined the vaginal flora of healthy pregnant women in 21 cases, and except in one case where a streptococcus and one in which a staphylococcus was present, no pathogenic organisms were isolated. Twelve of these cases were followed up after delivery and an examination of the uterine and vaginal swabs in the puerperium showed that the uterine swabs were sterile in 9 cases and contained only diphtheroids in 3, while the vaginal swabs showed mainly diphtheroids and yeasts.

THE USE OF FISHES FOR THE CONTROL OF MOSQUITOES.

By SUNDER LAL HORA, D.SC.,

Officiating Superintendent, Zoological Survey of India (Indian Museum, Calcutta).

(Read at the Fourteenth Annual Meeting of the Indian Science Congress and published with permission of the Director, Zoological Survey of India.)

DURING the last couple of decades great advance has been made regarding the study of fishes in their relation to the mosquito problem. The subject is, however, still in its infancy and a lot remains to be done. I have been able to collect 53 references on the subject, of which 13 deal with this problem in India. In our country great ignorance prevails, and to prove the utility of the finny tribe for the eradication of malaria and other diseases spread by the agency of mosquitoes extensive field observations are needed. For whatever knowledge we possess on the subject in India we are greatly indebted to the Madras Fishery Department, to Major R. B. S. Sewell, I.M.S., and to Dr. B. L. Chaudhuri.

My attention has been repeatedly drawn to this subject since I have been in charge of the fish collection in the Indian Museum after the retirement of Dr. B. L. Chaudhuri in 1921. We have received enquiries from malaria medical officers stationed in India and Burma and from several other gentlemen interested in the eradication of malaria. The last enquiry, which stimulated me to collect the information detailed here, came from Lieut.-Col. S. R. Christophers, F.R.S., I.M.S., Director of the Central Research Institute at Kasauli. He wrote to Major Sewell, "I have had a certain number of enquiries as to possibility of obtaining mosquito-eating fish. I believe at one time the Bengal Fisheries did supply certain species for trial in anti-malaria work. Possibly there are other sources. Would you very kindly let me know whom I might with advantage communicate with in this matter?" There is no separate Fisheries Department in Bengal now and the Director of Agriculture, who is in charge of the fisheries, has informed me that though the late Fisheries Department used to supply fish that feed on mosquito larvæ it is not possible for the present fishery officers to do the same now.

There is no fishery department in Bihar and Orissa, the United Provinces, Assam, Burma, the Central Provinces or Bombay, and I have ascertained from reliable sources that no organisations exist in these provinces which could undertake to supply larvicidal fishes. There is a fishery department in the Punjab with its head office at Dharmsala. The department has no experience of this business as they have never had any great demand for the supply of larvicidal fish. They do not breed them, but the Warden of Fisheries informs me that he "could arrange to have them collected to meet a limited demand within the Province."

The Department of Fishery, Madras, is the only organisation that can supply larvicidal fish at present. They generally keep in stock *Aplochilus melanostigma*, *Panchax parvus* and *Panchax striatus*. All of these are of proved utility for destroying mosquito larvæ and a few years ago they were extensively used for anti-malarial work. Dr. B. Sundara Raj, Director, Department of Fishery, Madras, has written to me that there is very little demand for larvicidal fish in his province in these days. At my request he has estimated the cost of supplying 100 specimens at a distance of 100 miles from Madras by railway at Rs. 4 only, but if the fish are to be sent to a great distance "a trained attendant will be necessary to look after the fish during the journey, in which case, his railway fare 3rd class to and from his station plus 4 annas *batta* per day will have to be paid." This Department has issued a leaflet giving detailed information and has published an illustrated pamphlet entitled *A Note on Treatment of Swamps, etc.*, by Mr. H. C. Wilson, available at the Fisheries Bureau, Chepauk, Madras. Major Sewell and Dr. Chaudhuri's pamphlet on *Fish of Proved Utility as Mosquito Larvæ Destroyers* is fairly well known among medical people interested in the problem of malaria.

As I have already pointed out, there is a great necessity for extensive field work in India and I hope that when the problem of malaria comes to be seriously considered in this country a fair chance will be given to fish also. There are two definite cases that have come under my personal observation and I think it will not be out of place to mention them here.

In May 1923, the Director-General of Ordnance in India wrote to us for "advice likely to be of use in dealing with the tanks at Cossipore and Ishapore" where numerous ordnance officials live near tanks. I was deputed by the late Dr. Annandale to conduct the enquiry. I visited the Seven Tanks Estate

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

at Cossipore on the morning of the 20th of June, 1923, and found that besides the big carps, such as *Catla catla, Labeo rohita* and *Cirrhina mrigala*, there were plenty of small fish of the typical larvicidal genera such as *Haplochilus, Ambassis, Chela* and *Barbus* (*Puntius*) and consequently after a survey of these tanks lasting for an hour and a half, I was only able to find one cast skin of a mosquito larva. To my great disgust I found a quantity of oily substance sprinkled over the surface of some of the tanks, which in my opinion under such circumstances does more harm than good. As I was indisposed, a similar survey was carried out by my colleague Dr. B. Prashad at the Metal and Steel Factory, Ishapur, and Nawabgunj with similar results. In February last a sudden fish mortality was noticed in the Museum tank at Calcutta and all kinds of fish died in hundreds. After this we found several species of mosquitoes breeding in our tank, but we introduced in time specimens of *Haplochilus panchax* and from occasional observations that have been made since then by our Entomological Assistant no mosquito larvæ have subsequently been found in the tank.

There are two fundamental preliminaries which should be carried out to give the larvicidal fish a chance to prove their utility. First the tanks and ponds should be cleared of weeds and overhanging vegetation, and secondly it must be ensured that "all predaceous fishes are removed as well, for otherwise, if you put in supplies of little larvicidal fishes, you will only be providing tasty morsels for these bigger fish. It is best, if possible, to drain out the tank and clean the bottom thoroughly before refilling and putting in small fishes. The murrel, which is one of the worst of our predaceous fishes, burrows in the mud and may have to be literally dug out, before the tank is safe." * I must here regret the action of certain fishery departments in India; these are busily engaged in the propagation of murrel and are introducing it into tanks and ponds all over their jurisdiction. I hope the time will soon come when they will realize the harm that they are doing and have done.

There is one further observation that I have to make on this subject and that is regarding importing larvicidal fishes either from outside India or from one province to another. It is highly desirable that experiments should be carried out on the local species and a selection made from them, for it is quite possible that an imported fish may give up its larvæ-eating propensities under a changed environment. I have in the end to lay great stress on this aspect of the problem and the solution of it lies in an extensive survey of the Indian Empire by a band of experts.

* From a letter of Mr. J. Hornell to Major-General L. R. Kenyon, C.B., Director-General of Ordnance in India.

Since the above was written I have read with great interest a short article by Malcolm E. MacGregor in the columns of *Nature* for September 4th, 1926, regarding *Medical Entomology and the Tropical Field Worker*. The conclusions arrived at are the same as those on which I have laid great stress above, namely, the desirability of the study of the "bionomics, the remarkable habits of some species, the practical methods of demonstrating the breeding-places in Nature, the varied methods of collection, the practical application of control measures in the field," by all sanitarians.

In this connection may I be allowed to mention the willingness with which the officers of the Zoological Survey of India have always co-operated with the medical authorities for the biological investigation of diseases. Drs. Annandale and Kemp carried out an extensive survey of the molluscs of India and its North-Western frontiers in connection with the possible occurrence of schistosomiasis and even at this time (January, 1927) Dr. H. S. Rao, at the request of the Director, Pasteur Institute, Rangoon, is engaged in the Mollusc Survey of the Northern Shan States with a view to study the possibility of the spread of schistosomiasis from the Chinese frontier into Burma. I have the permission of Major R. B. Seymour Sewell, Director, Zoological Survey of India, to say that we shall always be ready to co-operate on such problems where a knowledge of zoological research is a great factor in the investigation of a disease.

Major Sewell has very kindly drawn my attention to a special cablegram that appeared in the *Statesman* of the 29th October, 1926. It refers to a campaign all over the Empire against insects and weed pests advocated by Professor Tillyard, Chief of the Biological Department of the Cawthron Institute of New Zealand. He favours the method of "biological control—by introduction of hostile insects to fight the pests rather than the chemical method of spraying or fumigation, which, he said, was merely temporary and also costly." In my opinion similar biological methods will ultimately be found necessary for the prevention of such diseases of man and cattle where it is known that they are spread through the agency of insects or other animals.

FLOOD AND FLUSH SCHEMES—ANCIENT AND MODERN—WITH REFERENCE TO THE SITE OF THE ANCIENT CITY OF GOUR, MALDA DISTRICT, BENGAL, AND TO THE INCIDENCE OF MALARIA.

By SARASI LAL SARCAR,
Civil Surgeon, Noakhali.

GOUR, the ancient capital of Bengal, during the Hindu reigns and the greater part of the

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Mohammedan dynasty, was situated about 3 miles south of the present town of English Bazaar, the present headquarter station of the Malda District. At present there are ruins of this ancient and once glorious city in the form of old ramparts, big tanks, bundhs, side channels, a few towers, a few ruined or intact buildings, generally mosques. In these ruins there is a demonstration that the ancient city builders recognized very well an important point in sanitation, viz., the flooding and flushing system. In building up this ancient city of Gour this system was all along kept in mind. In another ancient city 5 miles from the town of English Bazaar, known at present as Nimaserai which is not in ruins like Gour the flooding and flushing system of the ancient times is still to a great extent in operation.

The fact of the existence of a flooding and flushing system in the ancient times came to my notice when I interested myself in investigating the cause of the highly insanitary condition of an area of about 60 square miles situated near the town of English Bazaar, which included the site of the old city of Gour. I noticed that there was an artificial canal system in the city of Gour, as well as in the neighbouring area, which flushed the city, irrigated lands for agricultural purposes, and had connexions with the tanks for filling these up and thus bringing annually fresh water into them. A few of these tanks were of a huge size worthy of the ancient capital, the excavation of which was possible in these ancient times because labour was cheap. The irrigation system was on a huge scale, with very big bundhs round very wide areas, into which flood water was admitted for irrigating the land for agricultural purposes and was then let out when this object had been attained. There are still indications in these canals of pucca brick work at places, with grooves for iron gates, and there were sluice gate arrangements in different portions of these canals for regulating the flow of water.

I found afterwards that there is a book relating to these ruins written by Mr. Ravenshaw, a former Collector of Malda, a long time ago. The writer of the book had the opportunity of observing then these canals and bundhs in a less altered condition than at present and he has given in the end of his book a diagrammatic sketch of the canals and bundhs. However, this diagrammatic sketch has departed widely from geographical accuracy as the sketch plan had not been drawn up after an accurate survey.

By appeals through the District Board the interest of the Public Health Department, Bengal, was aroused in the matter. The Engineering branch of the Public Health Department made a thorough local survey of the area. Mr. G. Bransby Williams, Chief Engineer, Public Health Department, Bengal, has very kindly given me permission to publish the sketch plan herein reproduced, which, in a very brief space, indicates the result of this local survey. This map is an accurate geographical representation of a part of the diagrammatic canal system given in Ravenshaw's book and thus has a historical and antiquarian value of its own. To understand this canal system fully the reader may be referred to Ravenshaw's volume.

In the sketch plan the reader will see the map of an area situated between two flowing rivers, the river Mahananda on the North and the river Bhagirathi on the South. There are several bundhs or embankments in this area which are represented by two rows of short parallel lines (like hills in an ordinary map). These bundhs have divided the area into several distinct big plots. These plots are like so many water-tubs and the Chief Engineer has indicated the points through which flood water of the river can be let in and let out into these artificial water-tubs. In bringing forward a new sanitary improvement scheme, the Chief Sanitary Engineer is thus trying to restore an arrangement which was in existence in olden days. Amongst these ruins we find at places the pucca brickwork structure of former sluice gates, and in these brickworks for sluice gates the remains of the grooves for sliding down up or the iron sluice gates can also be seen.

A sanitary survey of the area with a spleen census of the inhabitants was made by Dr. S. N. Sur, Assistant Director of Public Health, Bengal. The following are a few extracts from the report submitted by Dr. S. N. Sur on the 24th October 1921, to his department, which he has kindly permitted me to reproduce.

History.—The area in question is practically surrounded by old ramparts with side channels. These ramparts may be dated back to the period when Gour was in a flourishing condition, i.e., Lakshan Sen's time. The channels alongside these ramparts used to lead silt-laden water from the river Bhagirathi and other rivers when in flood, submerging the area and resulting in bumper crops and good health. About 25 to 30 years ago these channels were dammed at Lohagora and Darbasini to prevent flood water entering the area. This was probably due to damage of crops in 2 or 3 successive years owing to excessive flooding. This has been kept closed since then.

Result.—The result of this closing has been (1) an increase in the unhealthiness of the area; (2) a decrease in the output of crops; (3) want of good drinking water.

Increase of Malaria.—Thirty-one villages were inspected within the non-flooded area and 14 were inspected outside the bundhs—where flooding usually takes place every year. A list is attached herewith which shows that in all the villages in the flooded area—i.e., in

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the villages in which silt-laden water is introduced—every year the spleen indices are much lower. The average spleen index of all the children examined within the non-flooded area is 81.37 per cent. against 18.94 per cent. in the flooded area. This is a marked contrast. There is not a hard and fast line demarcating the two areas, but roughly the 45 villages are divisible into two classes. There are villages outside the non-flooded area which are practically not flooded and in these villages the spleen index is higher than in those which are not flooded.

This interesting report shows how the death-rate has increased and the birth-rate has decreased, the sickness-rate has increased; kala-azar has become prevalent; the yield of crops has become markedly diminished. In villages which were once in a populous condition there are remains of old huts which are now abandoned owing to deaths in the families. There are practically no tanks in these villages. Those which were in existence are placed alongside the channels, which now contain nothing but rain water and are full of vegetation. There is no current in them. These channels have become dangerous breeding places of carrier mosquitoes in the villages. The report suggests that these villages can be improved if silt-laden water be introduced into these channels during the monsoon which is the best breeding season for mosquitoes and when high temperature and humidity in the air is suitable for the growth of parasites in the mosquitoes.

The report records that several zemindars and big landholders objected to opening the bundhs. To quote from the report, "Owing to the failure of paddy crops year after year in some comparatively higher lands they have been turned into mango gardens and the objections to opening the bundhs come from those who have a vested interest in these mango gardens which bring them in a large profit. The owners of these mango gardens have greater influence in the country than the teeming millions who are daily suffering from want of sufficient food and from bad health. The number of deaths here also outnumbers that of births, which means depopulation. Are we to save these villages from depopulation by ignoring the vested interests of the rich, or to help the landlords by ignoring the real needs of the teeming millions?" On the other hand, some of the zemindars and big landholders who have lands at comparatively lower levels are against cutting the bundh, as they believe that thereby too much flood water will flow into their lands and will injure the crops. So here, as many other places in Bengal, the zemindars, big landholders, rich people with vested interests, ignore the real needs of teeming population of their lands.

During the flood time of 1922 the people of the locality, being educated by propaganda work to save themselves from death and destruction by the ravages of such epidemic diseases as malaria and kala-azar, stealthily cut the Lohagora bundh during the night. There was thereby a flow of flood water through a portion of the non-flooded area within the bundhs. This appeared to have a marked effect in improving the health of the locality. The cut portion of the bundh was not subsequently closed, owing to strong public opinion, and probably also because the landholders and zemindars who were in opposition found that they suffered no financial loss.

To test the effect of this flooding on the malarial epidemic the Public Health Department at my request again carried on a careful spleen census of the area in March 1925. The comparative tables of the splenic survey of the villages for the years 1921 and 1925 are here given side by side. In the comparative tables an attempt has been made to tabulate the villages according to the distance from the newly admitted flood water area. It will be seen that there has not only been a marked general reduction in the spleen rates—viz., from 18.8 per cent. to 10.1 per cent. in the flooded area and from 81.3 per cent. to 60.5 per cent. in the non-flooded area—but also that the villages actually flooded or closer to the newly flooded area show better results than the villages situated at a comparatively distant place.

The diminution of the spleen rate in the flooded area shows that a part of the infection of this area came from the non-flooded area. We took a spleen census of a part of both the flooded and non-flooded areas situated at a considerable distance from Lohagora bundh and thus not likely to be influenced by the admission of flooded water through the Lohagora bundh. These spleen figures are given in Table III. From this table it is evident that the general malarial infection in this area is practically the same as before. Moreover, the death-rate per mille of the population does not show much variation during these years.

The statistics for kala-azar cases—shown in Table IV—shows that kala-azar is more prevalent in the non-flooded area than in the flooded area.

Thus we have here tested definitely as in a scientific experiment, the effect of flooding as prophylactic measure against epidemic malaria and have found the result to be quite satisfactory. So it is most desirable that the scheme drawn up by the Chief Engineer, Public Health Department, Bengal, may be introduced into the area for restoring the area to its former healthiness and prosperity.

SUMMARY.

(1) There was a plan of city building in ancient days, utilizing the flood water for

flooding and flushing, which is worthy of being studied and followed in present times.

(2) A change of policy on the part of the zemindars, big landowners, and rich men with vested interests is necessary for the improvement of sanitation in this Province.

(3) The common people should be led to take the initiative in sanitary measures by propaganda work.

(4) The experiences at Lohagora bundh area prove definitely the good effects of flooding and flushing in checking epidemic malaria.

THE DELETERIOUSNESS OF POTABLE SPIRITS ON THE INDIAN MARKET.

By R. N. CHOPRA, M.A., M.D. (Cantab.),
MAJOR, I.M.S.,
Professor of Pharmacology (Department of Pharmacology, Calcutta School of Tropical Medicine).

THE potable spirits offered for sale to the public in India fall under three main categories:—

(1) *Genuine and fully matured spirits.*—Genuine spirits consist of a solution of ethyl alcohol in water, together with sufficient quantities of the by-products of fermentation to confer a characteristic odour and flavour to it. Any one with sufficient experience can distinguish between the three fermentation bases used, namely, cereal grain for whisky, grape juice for brandy, and products of sugar-cane for rum. In old days pot-stills were exclusively used for the distillation of spirits and larger quantities of esters, higher alcohols, etc., were left which were responsible for the characteristic flavour and taste. By storage in wooden casks changes are brought about in the character and amount of these secondary constituents with the result that the flavour is improved. All the matured spirits including whiskies, brandies, etc., are covered by a certificate of age to the effect that they are over three years old. Proof of maturation is by official certificates from the Government of the country exporting, stating the number of years the spirit covered by the certificate has matured in the wood. In Australia all spirits must be stored for two years in bond. In the Union of South Africa three years' bonding is specified for spirits other than gin and liquors. *The Immatured Sprits (Restriction) Act, U. K.*, 1915, laid down that all plain spirits intended for human consumption should be kept in bond for a period of three years before issue. It has not been specified whether the storage should be in wooden casks or not. This act, however, was not passed for hygienic reasons, but was primarily intended as a war measure to restrict the consumption of spirit in the national interest. It does not prevent the use of new spirits in the preparation of compound spirits such as gin, British brandy, etc., provided certain duties are paid. The retail price at which these spirits are sold is over Rs. 84 per dozen bottles, as the storing of spirits for long periods naturally increases the price. In practice most of the good brands of spirits are stored for considerably longer periods than the three years specified by the British and French excise regulations.

(2) *Genuine but immature spirits.*—These spirits are genuine in so far as they are made from the same fermentation bases as class (1). They are generally distilled by means of "patent stills," which are so arranged that an appreciable quantity of the secondary products, but much less than in case of the pot-still, is left behind. Long maturation is therefore not necessary for these spirits. There are quite a large number of such spirits on the market. The whiskies are the produce of Scotland and the brandy that of France, but they are said to be very immature spirits as they could not have been stored for long enough periods to mature owing to their very low price. The selling price of most of these brands is between Rs. 40 to Rs. 55 per dozen bottles.

(3) *Imitation or factitious spirits.*—A very large number of such spirits are now offered for sale. These imitation spirits consist of diluted alcohol which has been so far stripped of the by-products by means of effective "patent stills" that the fermentation base is no longer discernible, and certain odourous and flavouring substances giving the flavour and odour of the genuine spirits are added to it in minute quantities. Two things are required for making imitation spirits; firstly, ethyl alcohol, rectified spirit being generally used, and secondly, flavouring agents, usually added in form of essences. The composition of these essences varies according to the particular spirit that is to be made, and various firms have elaborated their own formulæ. The basic substances in all the essences are esters, peculiar to each spirits, e.g., ethyl butyrate, ethyl acetate and ethyl formate occur in rum; ethyl acetate and ethyl nitrite in whisky; and spirits of nitrous ether and amyl caprionate in brandy and cognac. These imitation spirits by analysis contain much smaller quantities of the by-products than a genuine spirit and therefore have a comparatively mild taste.

Of late years the Indian market has been flooded with many different brands of these imitation spirits—whisky, brandy, rum, etc., imported from Germany and other countries. These spirits are put into very attractive looking bottles with beautiful labels and are considerably cheaper than the "genuine spirits," the sale price being Rs. 20 to Rs. 40 per dozen bottles. They can be sold cheaply because inexpensive fermentation bases such as potatoes, rice, etc., are used in their preparation. On account of their low cost and milder taste the public prefer them and the demand for them appears to be rapidly increasing. The

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

question has therefore arisen as to whether these imitation spirits, on account of the cheap cost of their production owing to cheaper raw materials which are used in their manufacture, contain products which are more harmful than those contained in the genuine spirits.

DELETERIOUSNESS OF GENUINE MATURE AND IMMATURE SPIRITS AND IMITATION SPIRITS.

The harmful and toxic effects of spirits were in the past attributed to the by-products. The foundation of this belief rested on the fact that the first distillate from a mash in the case of pot-still liquors was very unpleasant and undrinkable. No one had paid any attention to the large quantities of ethyl alcohol which were present. The question was thoroughly gone into by the Playfair Committee in 1891, who came to the conclusion that immature spirits were not deleterious, but unpalatable. As regards the imitation spirits the same committee concluded that these spirits were no more harmful than genuine spirits. In those days very few of the imitation spirits were in use and only a limited number of flavouring essences were employed. In India the question was examined thoroughly by Sir C. H. Bedford in 1906 with special reference to alcoholic liquors produced in this country as well as of the liquors which were imported. A large amount of experimental work was done and the conclusions drawn were (*a*) that alcohol alone was at least as deleterious as alcohol plus by-products; (*b*) that the by-products, though undoubtedly noxious, in the relatively small quantities in which they are found in even the worst samples of potable liquors have negligible effects; (*c*) that spirit drinking was noxious because of the toxicity of ethyl alcohol; (*d*) that on hygienic grounds there was no reason to discriminate between most of the good quality of imported spirits, the cheap imported spirits, and the factitious Indo-European spirits. Cheaper spirits distilled from the cheap fermentation bases were not more deleterious than the better class spirits. The Royal Commission on potable spirits in 1909 confirmed in the main all the findings of the Playfair Committee and the Bedford report. Alcohol and not the by-products was chiefly responsible for all the toxic effects produced by potable spirits. Cheaper spirits distilled from cheap fermentation bases were not deleterious because of the by-products they contained, but because excessive quantities of alcohol were consumed which produced harmful effects.

It is obvious from this that while the toxicity of ethyl alcohol and the by-products produced during the course of distillation of potable liquors, which are responsible for the taste of the liquor, has been fully investigated, the toxicity of the essences used for purposes of flavouring the imitation spirits and the toxicity of the imitation spirits now largely consumed in this country has not been thoroughly investigated. Further, I am unable to find any experimental data to show whether the immature genuine spirits were any more toxic than the mature genuine spirits. As this matter is of great importance from the point of the health of the public, a large series of experiments were conducted at the instance of the Government of India to settle these points.

EXPERIMENTAL EVIDENCE.

A large number of animals, mostly cats, were used for this investigation. Batches of animals were kept in large cages in which they could move about freely and were given a routine diet consisting of boiled meat, fish and rice. They were carefully weighed before and after the experiments and watched for the appearance of any untoward symptoms. At the completion of the experiment the animals were killed and a careful post-mortem examination was made and any changes produced were recorded. Parts of all the important organs such as the liver, kidney, suprarenals, stomach, intestine, pancreas, lungs, etc., were removed for microscopical examination. This involved a very large amount of work and I am very grateful to my colleague Lieut.-Col. H. W. Acton, I.M.S., Professor of Pathology, Calcutta School of Tropical Medicine, for giving his expert opinion on the pathological findings. Two separate sets of experiments were arranged.

Experiments; Group A.—The first group were carried out in order to determine the toxicity of certain essences used in the preparation of imitation spirits now on the market. These included essences for preparing imitation whisky, brandy, gin and rum, manufactured by well known British firms. I used these in all my experiments, taking them as typical examples of the essences used commercially in preparation of imitation spirits.

(1) Ten per cent. solutions of the essences dissolved in 42 per cent. of alcohol (by volume) in water were given intravenously to intact animals under experimental conditions. There was no appreciable effect on the heart, blood pressure, respiration, or other organs of these animals. The proportion of the essence of whisky in ordinary imitation whisky is 1 of the essence in 5,333, so that when such spirits are consumed and circulate in the blood in much lower concentrations the effects produced will be negligible. Perfusion of the isolated mammalian heart, which is very susceptible to toxic substances, with 1 in 2,500 to 1 in 20,000 dilutions of the essence had only a slight depressing effect. In the human body these essences would not probably circulate in stronger concentrations than 1 in 100,000 to 1 in 150,000 and the chances of any direct action on this organ are negligible.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(2) Large quantities of the essences such as 30 to 60 minims in 4 c.c. of rectified spirit (B. P.) diluted 42 per cent. by volume were given to a series of animals by the stomach tube. No toxic symptoms either immediate or remote were noticed. In the dilutions in which they exist in the potable spirits their effect on the gastro-intestinal tract would be non-existent. Subcutaneous injections of pure essences in doses of 15 to 30 minims in a solution in diluted rectified spirit produced neither any general nor local, immediate or remote, effects.

(3) The lethal dose of ethyl alcohol to cats was 7 c.c. to 9 c.c., whether the essences were added to it in 1.0 c.c. doses or not. Symptoms such as intoxication, jaundice, and general toxæmia were not greater in the case of cats which were given alcohol plus essence, than in those which were given alcohol alone.

(4) A series of cats were fed daily for a period of one month (*a*) with 4 c.c. of alcohol largely diluted; (*b*) with the same amount of spirit plus essences in a concentration of 1 of essence in 250 to 500 parts of diluted alcohol. The animals of both batches were carefully watched during the experiment. They all lost weight and became thin and emaciated. At the end of this period these animals were killed and a thorough examination, both macroscopic and microscopic, was made of all the organs. Both groups showed marked gastro-intestinal catarrh and apparent changes in the abdominal organs. The histological changes, chiefly consisting of fatty infiltration, cloudy-swelling, fatty degeneration and increased formation of interstitial tissue, were confined chiefly to the liver and the kidneys. These were no more marked in those animals which were fed on rectified spirit plus essences than in those which received rectified spirit alone. As a matter of fact the animals which had the essences in addition showed a milder degree of pathological changes than those which had alcohol alone.

Experiments; Group B.—Thirteen specimens of the common potable spirits, including those considered to be genuine and fully matured, genuine but immature, and imitation or factitious spirits, were bought through the courtesy of one of the firms of wine and spirit importers and my investigations were mainly confined to these samples. Before proceeding with animal experiments all these samples were chemically examined with a view to determine, firstly if any methyl alcohol was present, and secondly to find out the exact quantity of ethyl alcohol present in every specimen, so that the dosage of each brand could be calculated exactly in terms of ethyl alcohol per kilo body weight of animals. The following table gives the result of the analysis kindly carried out by Mr. Jenks, the Chemical Examiner for Customs and Excise.

TABLE I.

13 *specimens of potable spirits (in bottle) offered for sale in the Indian market with original seals and capsules.*

No.	Description.	Real strength, alcohol % by volume (v/v)	Denige's test for methyl alcohol.	REMARKS.
1	Scotch Whisky	43·25	Negative	Matured.
2	Ditto.	44·24	Ditto.	Ditto.
3	Ditto.	44·85	Ditto.	Ditto.
4	Ditto.	43·37	Ditto.	Considered immature.
5	Ditto.	43·37	Ditto.	Ditto.
6	Ditto.	43·14	Ditto.	Ditto.
7	German Whisky	43·70	Ditto.	Imitation spirits.
8	Ditto.	43·76	Ditto.	Ditto.
9	Brandy French No. 1	47·13	Ditto.	Considered matured.
10	Ditto. No. 2	44·39	Ditto.	Ditto.
11	Ditto. No. 1	45·93	Ditto.	Ditto.
12	German Brandy	44·10	Ditto.	Imitation spirits.
13	Java Brandy, bottled in India	43·94	Ditto.	Ditto.

N.B.—The remarks' column shows the category under which these specimens were classed by commercial experts.

The effect of the different brands was then tested on animals. The results were as follows:—

(1) Intravenous injections of these spirits in intact animals in doses ranging from 0.1 to 1.0 c.c. produced exactly the same effects on the heart, blood pressure, respiration, etc. There is no reason to suppose that their behaviour will be different when they enter the circulation through the alimentary canal and circulate in very much smaller concentrations. On the isolated mammalian heart also in dilutions of 1 in 5,000 to 1 in 20,000 the depressing effects of all the different samples were equal. Further, the effects produced did not differ materially from those given by similar concentrations of pure ethyl alcohol. The lethal doses of all brands of spirits to cats were about the same and in terms of alcohol present corresponded to those obtained in the experiments in Group A (3).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(2) A large series of animals were divided into three batches and were fed for 10 days on doses of these spirits calculated at 1 c.c. of ethyl alcohol net per kilogram body weight of the animal. One batch was put on the genuine matured spirit, another on genuine but immatured spirits, and the third on imitation spirits. The dose selected was purposely small as cats are particularly susceptible to alcohol. Ten days was selected as the period during which this dosage was to be administered, as this period was found to be quite sufficient to produce changes in the animal organism without rendering the animal too weak and emaciated. All the animals lost in weight to the extent of 15 to 25 per cent. due in all probability to the general gastro-intestinal catarrh that was always set up very rapidly. After 10 days the animals were killed and all their organs were carefully examined macroscopically and microscopically. The organs chiefly affected were the gastro-intestinal tract, the liver and the kidneys; the changes were fatty infiltration, fatty degeneration, cloudy swelling, and increase of interstitial tissue. All the three groups of animals showed these changes in equal proportions.

(3) Two batches of animals were fed on large toxic doses of genuine fully matured whisky and brandy and two with imitation whisky and brandy. The doses were calculated on the basis of 4 c.c. of alcohol per kilo body weight. The average number of days of life, the loss in weight and the pathological finding, in different organs such as the kidney, liver and gastro-intestinal tract were the same.

DISCUSSION.

From the first group of experiments one is justified in concluding that the essences used for making factitious potable spirits now on the market are not toxic substances. As the imitation spirits are made from rectified spirit by adding small quantities of the essences to give the peculiar flavour of the liquor, it is reasonable to conclude that the imitation spirits are not deleterious because of the presence of these essences. The other important constituent is ethyl alcohol, which is common to both imitation and genuine spirits. From the analysis of the data obtained from the experiments in Group B one is justified in concluding that the toxic effects on animals of the three classes of spirits, i.e., genuine and mature spirits, immature genuine spirits, and imitation or factitious spirits are about equal.

Further, there is ample evidence to show that the fermentation base is not an important factor in the deleteriousness of potable spirits. Potato-spirits are not more deleterious than the sugar spirits or the grain spirits. Nine-tenths of the spirits consumed in Germany is potato-spirit, in Great Britain grain spirits are consumed, and in France and India sugar spirits are drunk. It cannot be imagined that potato-spirits are harmless to Germans but deleterious to an Englishman or an Indian, whether labelled whisky, brandy or gin: or that rectified grain spirit is harmless to all when taken as gin, but is deleterious when sold as cheap Scotch or imitation whisky. Sir Lauder Brunton, giving evidence before the Playfair Committee, suggested that the spirit distilled from rotten potatoes may contain tasteless alkaloids and other dangerous ingredients but the Royal Commission of 1909 failed to find any evidence of the presence of poisonous ingredients in such distillates. Gin containing one of these essences is largely consumed and no fault has been found with the British brandy in whose composition these essences occur. Further, the quantities of these essences in the imitation spirits is very small and no case of poisoning has been recorded from them. The higher alcohols and esters are present in minute quantities and the colouring matter is almost always the one used in genuine spirits (caramel), and also a duty approaching 1,000 per cent. of their value is staked on the quality of these articles.

From these considerations and from the data I have gathered from my experiments, I am justified in drawing the following

GENERAL CONCLUSIONS.

(*a*) The essences used in the preparation of imitation spirits are not deleterious to the animal organism, even when consumed in much larger quantities than those present in these spirits.

(*b*) Genuine and fully matured, genuine immature, and imitation or factitious spirits are equally deleterious to animals.

(*c*) Ethyl alcohol is mainly responsible for the deleterious effects of potable spirits; the by-products occur in such small quantities that their effect is negligible.

(*d*) The danger of cheap spirits (immature genuine, and imitation) lies in the fact that the consumer takes larger quantities, partly because of their low cost and partly because of their milder taste.

I gratefully acknowledge the help and advice given to me by Lieut.-Col. H. W. Acton, I.M.S. and Mr. R. L. Jenks in the course of this research. To Drs. Premankur De, Khem Singh Grewal and N. K. Basu I am indebted for much help in the experimental part of the work.

FURTHER OBSERVATIONS UPON "DERMAL LEISHMANOID."

By ASSISTANT SURGEON BIRAJ MOHAN DAS GUPTA, L.M.P.,

Assistant Professor of Protozoology, Calcutta School of Tropical Medicine.

A VERY considerable number of cases of this condition are now referred to this department for diagnosis from Colonel Acton's skin outpatient clinic at the Calcutta School of Tropical Medicine since attention was first drawn to it, and at least two fresh cases are seen every week.

In the early stage of the disease, when the lesions consist of white, non-pigmented tiny spots on the skin, it is very difficult to find parasites in the affected tissue. In all I have examined about ten such cases, and in only one—and then only after prolonged search—was a leishmania parasite discovered in the direct smears. On the other hand if a tiny fragment of infected tissue be snipped out and sown into NNN medium, a positive culture of *L. donovani* flagellates usually results. In one patient, for instance, although prolonged examination of three smears directly from a lesion had proved negative, cultures were positive.

On five occasions cultures were contaminated by staphylococci or by a stout organism resembling the "bottle bacillus" associated with acne. This was also present in the smears from the crushed tissue, although all precautions had been taken to sterilise the skin before a fragment of the growth was snipped off.

Later, when the granulomatous nodules have developed, the examination becomes very much easier: a tiny bit of the nodule is excised, crushed in saline, smeared on a slide, stained, with Leishman's stain and examined in the usual way. The smears thus prepared almost always show *L. donovani*—and not infrequently in very considerable numbers. Cultures can also be taken from the nodules in a similar way to those taken from an oriental sore. The skin over the nodule is sterilised with tincture of iodine and the material for inoculation obtained by puncturing it with a small hypodermic syringe fitted with a needle of relatively large bore; e.g., a Collin's 1 or 2 c.c. syringe fitted with a 5 c.c. needle has been found preferable to any other kind. Aspiration is made, and the material obtained sown directly into the water of condensation of NNN medium and incubated at 22°C. for 5 or 6 days. Cultures taken by this technique have never gone septic and have invariably been positive.

In a previous communication I have pointed out that the condition of "dermal leishmanoid" is a purely cutaneous one and never associated with visceral infection, the cultures of the blood—and in a few cases of liver juice as obtained by liver puncture—remaining sterile and negative for parasites. A different finding has recently been made, however, and brief notes on the case may not be without interest.

The patient, a Hindu lady, aged about 20 years, developed granulomatous nodules on the nose. These were first noticed about five months before she came under examination, when they looked like minute papules. Prior to this, she stated that tiny leucodermic spots had appeared on the same region and on the forehead, and that these leucodermic spots had disappeared without treatment with any medicament. She had been suffering from fever for the past eight months or so, and was treated with occasional doses of quinine without benefit. The spleen and liver were not palpable, and the aldehyde reaction was negative.

Blood culture, taken from a vein in the antecubital fossa, gave a rich growth of *L. donovani* flagellates upon the 11th day of culture. It is therefore clear that this patient had kala-azar simultaneously with "dermal leishmanoid."

Several cases of "dermal leishmanoid" have been reported following after an attack of kala-azar, and others who came from endemic areas of the latter disease, but who give no history of previous kala-azar or of fever or enlargement of the spleen or liver. In these culture of the venous blood from the antecubital fossa has hitherto been with negative results, and where liver puncture juice has been cultured the results have also been negative.

The question now arises as to whether the parasite of "dermal leishmanoid" will give identical serological reactions with *Leishmania donovani*, and this problem is now under study—using the technique adopted by Noguchi. Whatever the exact pathogenesis of "dermal leishmanoid" and its exact ætiology, the condition is clearly very far from uncommon in Bengal.

THE DIFFERENTIAL DIAGNOSIS OF SMALL-POX AND CHICKEN-POX.

By J. W. TOMB, O.B.E., M.D., D.P.H.,

Chief Sanitary Officer, Asansol Mines Board of Health.

THE differential diagnosis of chicken-pox and small-pox is of the utmost importance from a public health point of view, but experience in the Asansol Mining Settlement has shown that few medical practitioners in this part of Bengal are capable of making the diagnosis correctly. A not dissimilar state of affairs would also appear to exist in general elsewhere. The reason for this is that the text-books fail to lay sufficient stress on the fact that the only point in the differential diagnosis of the two diseases in which no ambiguity lies is the period of time which elapses between the onset of fever and the appearance of the characteristic "vesicular" eruption which is the common and striking feature of both diseases.

The Asansol Mines Board of Health was created by the Government of Bengal in 1913 "to prevent the outbreak and spread of dangerous epidemic diseases," one of the diseases referred to being small-pox, periodical

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

outbreaks of which had for many years inflicted severe economic loss on the coal industry of the province. On the active establishment of the Mines Board of Health it became obligatory on colliery managers within the Mining Settlement to give immediate notification to the Board of all cases of small-pox occurring on their collieries, but it was soon discovered that this order was ineffective, as the colliery doctor babus secured its evasion by the simple procedure of diagnosing *all* cases of fever accompanied by a vesicular eruption as "chicken-pox" and reporting the cases as such to their managers, obstinately refusing to recognise the existence of small-pox. A further order was thereupon issued by the Board calling upon colliery managers to notify to the Board all cases of sickness accompanied by a vesicular eruption as "small-pox." In consequence of this order all cases of chicken-pox as well as of small-pox became notifiable to the Board as "small-pox," and it therefore became necessary to have some means of differentiating easily and readily between the two diseases, not only for purposes of accurate record but for the guidance of the Board's outdoor sanitary staff in their work of disinfection, isolation and revaccination. In the printed forms provided by the Board for the notification of small-pox two columns were then inserted—one showing the "Date of onset of fever" and the other the "Date of outbreak of eruption."

From the analyses of many hundreds of such notifications, together with a thorough investigation of the symptoms and history of each individual case it became evident that there were two distinct diseases, one possessing in general the clinical characteristics of chicken-pox—in which a vesicular eruption appeared *within* 24 *hours* of the onset of fever (sometimes even preceding the fever), and the other possessing in general the clinical characteristics of small-pox—in which the vesicular eruption did not appear until *after a period of at least* 48 *hours* from the onset of fever—the period varying between 48 and 96 hours in extreme cases, but generally lying in the neighbourhood of 72 hours. It was also found that no vesicular eruption ever appeared between the 24th and 48th hour after the "onset of fever." It was therefore impressed upon the outdoor staff that in future in investigating cases of fever accompanied by a vesicular eruption careful enquiry was to be made on what date the patient first had fever, and after what interval from the time of the onset of fever the vesicular eruption appeared, and action taken accordingly. During the cold weather of the year 1925-26 small-pox was widely epidemic throughout Bengal, and the Mining Settlement of Asansol was threatened with a serious invasion of the disease which was held in check by the vaccination and revaccination of a large number (84,570) of the total inhabitants of the Settlement (Pop. 329,353). Advantage was taken of the opportunity thus offered to carry out an experimental investigation into the validity of making the differential diagnosis between chicken-pox and small-pox by the time interval elapsing between the onset of fever and the outbreak of eruption alone.

During this period 65,795 revaccinations of the general inhabitants of the Mining Settlement were performed, of which 51,012 were successful, giving a general "success" rate of 77 per cent.

In addition to these—at the same time and with the same supplies of lymph—94 volunteers of varying ages were revaccinated who had suffered during the preceding 12 to 24 months from fever accompanied by a vesicular eruption which appeared within 24 hours of the onset of fever and had therefore been diagnosed as *chicken-pox*. Of these 94 revaccinations 70 were successful, giving a rate of success of 75 per cent. Of these 94 cases 20 had been revaccinated successfully within a period of 5 to 10 years previously.

One hundred and eight volunteers of mature age were also similarly revaccinated, who had suffered during the preceding 12 to 24 months from fever accompanied by a vesicular eruption which appeared after 48 hours of the onset of fever and had therefore been diagnosed as *small-pox*. Of these 108 revaccinations none were successful. Moreover, none of these adults had ever at any time been successfully revaccinated.

The conclusion was therefore drawn that the absolute immunity shown by the latter group to vaccinia was due to their recent protection with variola, the 94 cases that had been diagnosed as chicken-pox showing practically the same degree of non-immunity to vaccinia as the rest of the general population.

It is therefore claimed that the differential diagnosis of chicken-pox and small-pox by means of the time interval which elapses between the date of the onset of fever and the date of the outbreak of the characteristic eruption is simple, accurate and unambiguous.

In cases where (as has recently been alleged in England) a vesicular eruption is found to occur unaccompanied by fever or malaise of any kind (the so-called "mild small-pox" or "alastrim") diagnosis by this method is obviously impossible; but such cases if they ever do occur are of no importance from a public health point of view since they cause neither morbidity nor mortality.

Moreover, no record of the derivation of a severe from a mild outbreak of small-pox could be discovered by Chapin* in the United States of America.

* Public Health Reports, Washington, 24th December, 1926.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

A table is appended showing the results of revaccination in the three groups referred to, as well as the results of primary vaccination in a fourth group of cases carried out at the same time.

	Total number of re-vaccinations.	Number of successful re-vaccinations.	% Rate of success.	Total number of primary vaccinations.	Number of successful primary vaccinations.	% Rate of success.
General population	65,795	51,012	77%	18,775	18,773	99·9 %
Cases diagnosed as "Chicken-pox" ..	94	70	75%	0	0	0
Cases diagnosed as "Small-pox ..	108	0	0 %	0	0	0

SUMMARY.

In the Asansol Mining Settlement the differential diagnosis of chicken-pox and small-pox is simply and accurately made by ascertaining the time interval which has elapsed between the onset of fever and the outbreak of the vesicular eruption.

This period in the case of chicken-pox never exceeds 24 hours. In the case of small-pox the interval always exceeds 48 hours.

65,795 inhabitants of the Asansol Mining Settlement were revaccinated during the financial year 1925-26, of whom 51,012 were successfully revaccinated, giving a rate of success amongst the general population of 77 per cent.

94 cases of chicken-pox (of recent incidence) as diagnosed by the time interval elapsing between the date of onset of fever and the date of outbreak of eruption were revaccinated at the same time, amongst whom the rate of success was 75 per cent.

108 cases of small-pox (of recent incidence) as diagnosed by the same method were also revaccinated at the same time, amongst whom the rate of success was nil.

CONCLUSION.

The differential diagnosis of chicken-pox and small-pox by means of the time interval elapsing between the "date of onset of fever" and the "date of outbreak of eruption" is accurate, simple and unambiguous and should be adopted in India by all Public Health authorities since any intelligent subordinate can thus make the diagnosis quickly and accurately.

LATHYRISM IN THE GILGIT AGENCY.

By LOUIS H. L. MACKENZIE,
MAJOR, I.M.S.,
Civil Surgeon, Hazara.

LIEUT.-COL. R. MCCARRISON'S "Notes on Lathyrism in the Gilgit Agency" published in the *Indian Journal of Medical Research*, Vol. XIV, No. 2, last October prompt me to send in such scanty notes as I have made on the same subject.

I was Agency Surgeon in Gilgit from 1921 to 1924, but it was only during my last year there that I became aware of the existence of lathyrism in the Agency.

The manner of my "discovery" was as follows:—

A member of the Gilgit scouts when at Gilgit for annual training was referred to hospital for examination as to his fitness for service. I was on tour at the time, but the case was mentioned to me on my return. The Assistant Surgeon told me that the man was pronounced unfit on account of paralysis of the legs, the symptoms being, he stated, those of a well known local disease supposed to be incurable. Further enquiries elicited the following information concerning a condition which is fairly widespread and popularly recognized but, owing to its reputation of being incurable, is never in my experience seen among hospital patients.

The essential feature of the disease is spastic paralysis of the legs.

It occurs in males—adults and children—but not in women, and is attributed to the eating of *gharash*. The condition occurs only in those whose diet consists of *gharash*, grown in newly cultivated land, the same plant after a few years' cultivation apparently losing its power to cause the disease.

Sufferers were stated never to recover but never to die from any state attributable to the condition. The victims are known locally as *gharashlang*, i.e., lame from *gharash*.

I visited some villages where the condition was reported to be common and saw all the available sufferers. The disease I found on enquiry, is attributed to a diet of *gharash* alone. If mixed with wheat, etc., it is said that no symptoms occur. Further, it was alleged that the disease occurs only when the *gharash* is grown on virgin soil, and the liability to it, even with an exclusively *gharash* diet, dies out in the course of a few years.

All the cases I saw—about a dozen—were males, and the age of onset varied from 5 to 55 years.

In most cases the onset was sudden, in other cases there was a vague history of some preliminary symptoms.

Some improvement was usually said to occur spontaneously in the course of years, but never

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

complete recovery. The general health remained good. On examination there was more or less marked spasticity of both thighs and legs.

Wasting was not noticeable.
Knee jerks as a rule were exaggerated.
Sensation, normal.
Bladder and rectum functioned normally.

A specimen of *gharash* which I sent to Major R. N. Chopra, I.M.S., of the Calcutta School of Tropical Medicine was identified by him as *Lathyrus sativus*.

These notes, so far as they go, correspond in the main with Colonel McCarrison's observations at Matamdas. The villages where I saw my cases were in Nagar territory between Chalt and Nilt, some 25 miles from Matamdas. I was led to believe that the condition was known throughout the Agency as liable to occur in newly cultivated areas. The immunity of females is generally accepted and appears remarkable.

Unfortunately I had no further opportunity of investigating the condition before leaving the Agency.

[*Note.*—Lieut.-Col. R. McCarrison, I.M.S., to whom Major Mackenzie's notes have been submitted, writes, "Major Mackenzie's notes on lathyrism in Gilgit are of interest. They emphasize a point, referred to in my note on lathyrism in the Gilgit Agency, which may be of scientific interest; the belief that *garash* (*Lathyrus sativus*) is only harmful when grown on virgin and barren soil. The other point of great interest, to which I also referred, is the peculiar sex incidence of the condition. For the rest, the condition as reported by Major Mackenzie is identical with 'lathyrism' as I have known it in Gilgit."—EDITOR, *I. M. G.*]

A STUDY OF THE INCIDENCE OF TUBERCULOSIS IN CALCUTTA AS EVIDENCED BY THE VON PIRQUET CUTI-REACTION.

By B. N. GUPTA, O.B.E., M.B.,
and
HIRAN K. DUTT, M.B.,
Laboratory, Howrah General Hospital.

TUBERCULOSIS has now been acknowledged as spreading daily in cities like Calcutta, and its prevention presents a difficult problem both to the public and the profession. In Calcutta alone the number of infected cases is more than 10,000 at the moment and in Bengal the number of cases must be a lakh at a moderate estimate. Extensive experimental investigations as to the nature of the disease and the adoption of suitable preventive measures have considerably brought down the incidence of the disease within recent years in several countries in Europe. The importance of the study is now being felt by the leading members of our profession who think about the future of our race, for this fell disease invalidates or carries away individuals when they are most likely to be useful to society (i.e., youths).

In carrying out von Pirquet's test to ascertain the incidence of the disease we were greatly helped by Col. D. P. Goil, I.M.S., for kindly placing at our disposal the District Jail. We are also grateful to Dr. A. C. Ukil of the Clinical Research Association for supplying us with samples of tuberculin and antigens for the compliment-fixation tests. We have used two kinds of tuberculin in our investigations, namely (1) Tuberculin Diagnose of Behringwarke, and (2) Tuberculin Brute of the Institut Pasteur, Paris. These appeared to us after several trials to have no differences as regards the results. The method employed was the standard method of putting a drop of tuberculin on the skin of the forearm, with a drop of carbolised saline as control, after previously cleaning the part first with soap and water and then with rectified spirit. A few scratches were then made through the drops with a sharp bayonet-shaped needle. Care was always taken to prevent the appearance of blood—the idea being to just open out the lymph spaces. We have found that this method of doing the test was far superior to the method of scratching with a scalpel or a vaccination lancet, as there is always a sort of uniformity in the procedure and a lack of inflammatory reaction consequent on vigorous scratching. We have endeavoured to study the incidence of the reaction according to age and according to profession wherever possible. The age factor appeared to us to be of great importance, as we wanted to know the percentage of children infected and the age of the highest incidence. Universal testing of children for the prevalence of tuberculosis is a measure which commends itself strongly. All who react are known to be infected. But it is fraught with difficulties as the parents strongly object to it, so our statistics are limited to children who visit the outdoor clinic or who are in the hospital (hospital classes), and the children in the free primary schools of the Calcutta Corporation who come from the poorer classes. The incidence among the middle class and well-to-do is considered to be lower than amongst the former classes.

We have endeavoured to find out the incidence among the children in infected houses, but have been successful in only three instances. The results are interesting in that in one house where there had been five deaths from tuberculosis, out of nine children eight were tested and four reacted to tuberculin. The two sons of a father dying of tuberculosis—aged 14 and 11 respectively—both reacted strongly to the test. Two babies aged 11 months, and 13 months and a child of 2½ years failed to react. A baby of 1½ years suffering from broncho-pneumonia was not

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

tested. In a second house there had been two deaths from tuberculosis and there were three children, of whom a boy aged 7 years reacted strongly to it. On examination the first author detected that the boy had a few slightly enlarged glands on one side of the neck and an irregular mass about the size of a small orange in the left hypochondriac region which did not move with respiration. There was no history of fever lately, though the boy had suffered from irregular fever when he was about 3 years of age. In a third house there had been two deaths from tuberculosis of which one was definitely diagnosed as pulmonary, the other was of unascertained anæmia and emaciation with diarrhœa, put down by the attending physician as tubercular. A third individual is suffering at present from pulmonary tuberculosis. There are two children in the family, aged 5 and 3 years, and neither reacted to the test. But all the adults with the exception of an old lady reacted to tuberculin. The two male members, both watch-repairers by occupation, reacted strongly. The high percentage in this particular house was dependent upon the social status of the individual. Watch-repairers are poorly paid and have to work hard throughout the day. These two are also addicted to alcohol and both are poorly built. The family live huddled up together in the lower flat of a small ill-ventilated house. It is a curious thing to note how the children escaped infection.

The cuti-reaction by the tuberculin test is a simple allergic phenomenon. It is an evidence of hyper-sensitiveness to the tuberculous toxin which can only be acquired after an individual has had to face an infection. From our statistics it is evident that we did not get a positive reaction in the first 5 years of life in the few cases we examined, and the percentage of positive reactions grew with the increase of age. The child is perhaps more susceptible than the adult but the defensive factors being weak it easily succumbs to infection. The death-rate of children from tuberculosis, especially from tubercular meningitis, if properly investigated—will alone clear the doubts about the incidence among them.

We have usually applied the tests only once in each individual. But in the jail we have used on some positive cases the intradermal method of inoculation to find out the degree of hyper-sensitiveness. We made different dilutions of tuberculin as 1/1,000,000th, 1/100,000th, and 1/10,000th mgm. With a tuberculin syringe and a very sharp needle supplied by Parke, Davis & Co. with their tuberculin syringe—we made three inoculations in the forearm after sterilizing the skin with alcohol and wiping it dry. The inoculations are made from the lowest dilutions first and the others in a vertical line upwards about one inch apart. Previous to the tuberculin we also inoculated an equal amount of saline as control. The dose used for all cases was 0.1 c.c.

Our observations with this method led to some very interesting results. All those who had a strongly positive cutaneous reaction reacted with all the three doses of tuberculin, with the general symptoms of malaise and a slight rise of temperature. The others who were positive with the scarification method gave varying results. Some reacted to all three, some with the second dilution, and a few only with the first. In this connection we would mention that we always employed this test to find out the degree of hyper-sensitiveness of a certain tubercular patient before giving him tuberculin as a curative; for from the reaction obtained, we used to ascertain the preliminary dose suitable for the individual.

Out of 1,000 males examined, 319 reacted to tuberculin, making the percentage of positives 32. Of the few females examined, most of them were between 30 and 60 years of age, and the percentage of positives amongst them was 37 per cent.

Result of von Pirquet's test according to age.

Age.	Number examined.	Number Positive.	Percentage
3 days — 5 years ..	20	Nil	Nil
6 years—10 years ..	280	50	18
11 „ —20 „ ..	210	60	28.5
21 „ —30 „ ..	470	150	32
31 „ —40 „ ..	310	150	48.4
41 „ —50 „ ..	110	70	63.6
51 „ —60 „ ..	30	21	70

Classification according to occupation.

Cultivators	30%	Positive.
Police	33%	"
Coolies	33%	"
Hawkers	37%	"
Mill-hands	50%	"
Servants	50%	"
Mistries	57%	"
Carters	66%	"
Brewers	100%	"
Sweepers	100%	"
Printers	100%	"

Though of course one cannot draw any definite conclusions from these figures, as all the classes were not equally represented, still the higher percentage amongst printers, carters, and sweepers is worth noting. The overcrowding and exposure to which carters and sweepers are liable make them especially prone to tuberculosis. In the case of printers the conditions of the influence of occupation on the causation of the disease as laid down by the late Sir William Osler are best fulfilled, such as "insanitary surroundings, exposure to dust, close confinement, and long irregular hours and low rates of wages."

In conclusion, we beg to state that we had to face innumerable difficulties in making the tuberculin survey by means of the cutaneous reactions. Custom and prejudice stood in our way. We know from statistics that the prevalence of the disease is greater here in women than among men. It is partly due to the *purdah* system, early child-bearing, and other social evils, but we could not try the tests on a sufficient number to find out the incidence of the disease among them. The few cases we got were from the outdoor dispensary, indoor patients, and a few from the houses of some liberal-minded patients. This is a sort of beginning and we hope to carry on our investigations in the future.

THE CAUSAL ORGANISM OF CHOLERA.

By F. J. PALMER, F.R.C.S.I.,
LIEUT.-COL., R.A.M.C. (Retd.),
Binnakandy, Cachar, Assam.

CHOLERA is almost universally attributed to the cholera vibrio, first discovered by Koch in 1883, and accepted, though not entirely without faint murmurs of questioning, since.

A doubt seems always to have existed as to the actual rôle played by the cholera vibrio, partly owing to the fact that a disease resembling cholera cannot be produced in experimental animals.

Whilst to a certain extent this doubt persists, and is reflected in textbooks, in other respects the teaching of these textbooks is dogmatic enough. All refer to the enormous number of comma bacilli present in films made from the stools, and the "fish in a stream" appearance is alluded to in Manson, etc. Muir and Ritchie mention that "in the characteristic rice water fluid in the intestines they occur in enormous numbers, almost in pure culture."

This may be taken as a type of textbook pronouncement.

On the other hand, Maitra and his co-workers are much less dogmatic, and the former, (*Indian Medical Gazette,* March 1925) described a cholera-like disease of low infectivity and moderate severity, in which vibrios were absent in smear and culture.

In the *Indian Medical Gazette,* July 1925, Maitra very plainly voices his doubts as to the columnar sharp-staining epithelial cells. The organism figured and described does not at all resemble the one to be hereafter mentioned, but I have been able on a couple of occasions to recognise epithelial elements, a little less necrosed than usual. This I attribute to a shorter action of the toxin owing to early treatment.

In the *Indian Medical Gazette,* July 1925, Maitra very plainly voices his doubts as to the characteristic textbook appearances. I quote from his paper. "Our experience, however, is not in accord with that of the reviewer or of the textbook writers. During our investigation we often came across cases in the acute stage where no vibrios were visible, but nevertheless they were cultivated successfully on special media."

Whilst in his March paper Maitra approached closely to the conception of two varieties of cholera—a non-spreading less virulent type, not due to vibrionic infection, and a more virulent spreading type due to comma bacilli—he gradually receded from this position, and in his third paper (*Indian Medical Gazette,* December 1925) came to the conclusion that all clinical cases of cholera were associated with vibrionic infection. His adherence to the orthodox view is also shown in the summary of work published in the report of the Calcutta School for 1925, though the case for vibrios is distinctly weakened by the statement that blood agglutinations to Koch's vibrio varied from 1 : 10 to 1 : 200. This is a very different figure from the 1 : 1000 of Manson and Muir and Ritchie, and not nearly so impressive.

In this connection I should like to record my opinion that the isolation of an organism by intensive cultural methods, when little other evidence of its presence exists is rather weak evidence of its causal relationship. The intestinal flora is a rich and varied one.

The writer first became interested in this subject whilst in Mesopotamia, and can

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

remember distinctly several occasions in which prolonged search failed to find anything resembling the comma bacillus, though numerous spirochætes—*S. eurgyrata*—were a pretty frequent finding. This might be attributed to lack of skill and technique, and I was at first inclined to consider my failure as due to this cause. Subsequent experience has shown me that the textbook teachings are in some respects inaccurate.

It was during the cholera season of 1925 that the writer first began to closely study films made from the stools of cholera cases, with the idea of so familiarising himself with the appearances presented that the diagnosis of cholera could be made otherwise than clinically. Every year sporadic cases and small outbreaks of clinical cholera occur in the tea gardens of which the writer has charge; and occasionally larger outbreaks are seen, as happened in the first hot weather of the writer's residence, when unfortunately there was neither time nor facilities for microscopic examination. It was quickly found that a good deal of persuasion was necessary to overcome inertia and obtain specimens. This was gradually remedied, and last year I was more successful in obtaining smears than in any previous year.

In another respect I was not so successful. Desiring to obtain smears from cases of severe diarrhœa, so that results might be collated, and the presence or otherwise of any definite organism be excluded, I found myself against a blank wall. It was explained to me that the coolies feared that if their stools were microscopically examined the cholera "poka" might be found, and that they would then be isoloted for three weeks.

After this preliminary explanation I shall proceed to a description of the appearances obtained.

I may first state that I am in complete agreement with Maitra and his co-workers with regard to the presence of degenerated cellular elements, with hazily staining nuclei remaining in cholera stool smears, and like him consider that their appearance is so characteristic that a diagnosis of cholera may be based on their presence or otherwise.

I also agree with him as to the difficulty of finding comma bacilli. It is pretty common to find slender, bow-like, curved rods, about the size of a tubercle bacillus, but I have only very occasionally found anything resembling a comma bacillus, and then only after a good deal of searching.

But in the greater number of the cases which I have had an opportunity of examining, some sixty in all, another organism seemed to be so frequently—and in many cases so predominantly—present that the microscopic picture presented was very different indeed from the classical description.

I had for some time speculated as to whether there might not be two varieties of clinical cholera; one caused by the classical type of vibrio, and another of different causation. This view was originally based upon epidemiological factors, and seemed to receive a certain amount of confirmation when in some cases towards the end of the cholera season of 1925, I first recognised what seemed to me to be a characteristic organism of a type hitherto undescribed. I was aware of Maitra's paper in the *Indian Medical Gazette* of March 1925, in which he mentioned a small outbreak of clinical cholera in which he found short rod-shaped bacilli in clumps amongst a columnar celled epithelial exudate. The description and the micro-photograph given do not however bear any resemblance to the organism noticed by me.

The reason why one was inclined to consider that there might be a second disease clinically resembling cholera was the fact, to which perhaps I may have assigned undue importance for a time, that some of these sporadic cases, though of severe type and showing a high mortality unless treatment was begun early, did not seem as inclined to spread as one might imagine *a priori* would be the case. Though not entirely prepared to discard this view and deny altogether the existence of two diseases, or a para-cholera, I have inclined for some time past to the view that the infectivity of cholera may have been exaggerated. In this district, as far as I can gather from conversation with old residents, cholera tends to appear more regularly every year than formerly, when it was said only to visit gardens at longer intervals, and when it did so produced more severe epidemics. It has never been absent during a whole year from some of the gardens of which I have charge for the past 3 years, and appeared again in 1926. Bengal is recognised as the endemic home of cholera. As the population of this district, and the transport facilities between it and Bengal increase it may be possible that we are witnessing a gradual extension of the endemic area, and that the spread of the disease from the surrounding villages to the tea garden population is being more interrupted than hitherto by such measures as disinfection of wells, prophylactic acid to contacts, and the dawn of some idea of epidemiology in the mind of the tea garden coolie. Should there be anything in this idea, the epidemiological argument in favour of there being two kinds of cholera, the spreading and non-spreading types, loses some of its weight. It may be only a case of infectivity.

In a paper read at the Annual Meeting of the Assam Branch of the *British Medical Association* in March 1925, I touched on some

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

aspects of cholera epidemiology and tentatively advanced the hypothesis that sporadic cases were due to a minor water infection, and more severe spreading epidemics to a more massive infection. Something of the same kind is already supposed to exist in the case of spirochætal jaundice, in which the spirochætes at some seasons are conjectured to increase so much in numbers as to be capable of infection.

I may remark here that according to the papers, such as the *Statesman*, Calcutta shows weekly some 20 deaths attributed to cholera during the warm months. If the vibrio must produce spreading epidemics, what are these cases? Are some possibly non-vibrionic? The truth probably is that, whatever the cause of cholera may ultimately prove to be, the diffuse spreading epidemic can only occur as the result of heavy mass infection in a population entirely indifferent to the crudest ideas of sanitation, and where perhaps the initial virulence of the organism has become greatly exalted by frequent passages. My experience inclines me to believe that the infectivity of cholera may have been somewhat exaggerated.

For a considerable time past I have noted the close connection that seemed to exist between such festivals as marriages, etc. and cholera, but attributed it to the increased susceptibility induced by indigestion following excessive eating and drinking. As I mentioned in a previous paper, read at the Annual Meeting of the Assam Branch of the British Medical Association in 1926, cholera seemed to me an ordinary attack of indigestion plus the cholera organism.

My idea then, and for a time, was that Gargantuan feasts of ill-cooked flesh, washed down by copious libations, in people who were generally rice and vegetable feeders fully accounted for the increased susceptibility. It was only during the cholera season of 1926 that it dawned upon me that another explanation might be possible, and that a more intimate connection might exist In several cases small group outbreaks took place, confined to the guests at a marriage or funeral feast, and in these cases a pig had been killed and eaten. The cleaning and cooking seemed to be of the crudest description. As far as I could make out after inquiries made, the animal is first laid on a fire to singe the hairs. It is then opened and the intestines removed. These are cleaned by stripping through the fingers, and a perfunctory rinse in water, and are often only half cooked when eaten.

If this incidence of clinical cholera after such feasts of swine flesh is not a mere coincidence, it may prove that that well known foul feeder the pig is a reservoir of infection, and our admiration for the sanitary wisdom of the Mosaic law may receive an added fillip.

But even if a close connection between the organism of perhaps one kind of cholera and the pig should be proved to exist, this would only account for localised outbreaks. For epidemics it would seem necessary to assume infection of the water supply.

It would be interesting to obtain the relative number of Hindus and Moslems affected by cholera in a district where the populations are approximately equal.

I wish particularly to emphasise that these were not trivial cases of gastro-enteritis, but were clinical cholera, with collapse, rice-water stools, and grave symptoms generally. One such group of six cases occurred amongst the guests at a wedding which unfortunately took place within a stone's throw of my own bungalow, all of which were seen by me. All were typical cases with collapse, suppression of urine, cramps, etc. One died, and two others very nearly did so. All passed characteristic stools, followed in some by mucus. The writer has had a long and wide tropical experience, and has not neglected his opportunities, and there is no doubt in his mind that these were cases of clinical cholera. The same applies to all the cases which were seen by him personally in 1926.

Towards the end of the cholera season of 1925 the writer in examining films made from the stools of clinical cases first began to notice in them numerous small oval cocco-bacilli. One film especially which showed at the same time numerous faintly stained spirochætes such as I had previously noticed in Mesopotamia, showed these in what seemed at first glance almost pure culture, owing to the faint staining of the spirochætes. So impressed was I by some of these specimens that a few were kept over to compare with those of the following year. I endeavoured also to make arrangements for the securing of two or three films from every case of clinical cholera occurring in my practice. Owing to the fact that the treatment adopted is by cresol and acid, I was at pains to stress the importance of obtaining films as early in the case as possible. This was done for two reasons; firstly because the causal organism was more likely to be present in large numbers before the bowel had been swept almost clear of contents, and secondarily because the acid used in treatment might lead to defective staining of some organisms which might be present. I also endeavoured to obtain films prepared from stools as soon after passage as possible to lessen the likelihood of organisms not originally present in the bowel increasing greatly in numbers after passage. A certain number of films were made by myself as opportunity offered. In every case instructions were

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

given that the film should be made from the shreds or so-called rice-grains of the stool. This however was not always very perfectly carried out.

Altogether over two hundred films from some sixty cases were examined in 1926. The first film examined showed a cocco-bacillus similar to that noted in the later 1925 cases, and nearly all the films since examined have given a similar finding, for unless the organism occurs in large numbers or characteristic grouping it may be difficult to distinguish solitary examples of the oval form from other rapidly dividing bacilli.

The organism is a small oval or boat shaped cocco-bacillus, sometimes occurring in enormous numbers in films and giving a "fish in the stream" appearance. At other times it occurs in frequent clumps or clusters. When the "fish in the stream" appearance is presented the organism generally stains homogenously, but at other times, and often in the clumps, an appearance of bipolar staining is presented which later seems in some films to suggest spore formation. There seems to be a certain amount of variation in size, shape, and dye-affinity at times: and when some portions of a film show well stained clumps, other portions may show somewhat similar clumps of faintly staining "ghosts," which seem larger and less distinct, and may be involution forms, or perhaps due to the acid used in treatment. The organism can be seen in enormous numbers in what appear to be portions of the desquamated bowel wall with faintly staining and necrosed nuclei.

The organism stains readily as a rule with methylene blue, gentian or methyl violet and carbol fuchsin.

The appearances presented suggest that some degree of pleomorphism exist.

In a few specimens I have seen bacilli with bipolar staining exactly resembling *B. pestis,* but not staining very sharply, and more deeply stained clear cut bacilli of the same size with a central spore in the same field, and it seemed difficult to resist the suggestion that they were the same organism.

Cultures at room temperature have been made from three cases only, each of which belonged to a different outbreak and garden. From the first, on ordinary agar a small central spore-bearing bacillus was isolated in white circular colonies, and appeared identical with that seen in the stools.

In the two later cultures I endeavoured to imitate the alkaline cholera stool, and made the agar quite definitely alkaline to litmus paper. In these no growth was visible for a couple of days, when the whole surface suddenly became covered with a barely perceptible film which gradually became more manifest, through which later other colonies appeared. This film appeared to be made up chiefly of a large and small central spore-bearer. The large spore-bearer was subsequently isolated from a control made from a rice eater's fæces. There are two varieties of small central spore-bearer, both of which I have seen in cholera films. The most common and the smaller shows a small oval central spore. The other, a little longer, shows a more elongated spore. Though both these forms have been seen in cholera films, the former is generally much more evident and is the one which may prove of pathogenic significance.

So far the small central spore-bearer has been cultured from three cases of cholera only, but not from the fæces of a rice eater and a European. The elongated spore-bearer has been cultured from a rice eater's fæces.

The small central spore-bearer forms a growth like white enamel in older cultures. The others are not so shiny in appearance.

In alkaline broth a pellicle growth appears on the surface after many days. A slender bacillus with three or four spores has also been isolated and organisms similar in appearance have often been seen in films, but I do regard them as of pathogenic significance.

Though in the stool films one appears to trace transitions between the oval coccus and the bi-polar staining bacillus, and between that again and the small central spore-bearer, all the culture forms of the small spore-bearer are alike in showing a spore from the earliest moment of growth. Possessing no incubator, I am unable to say whether these forms may not appear under more favourable conditions. At present their lack forms a missing link in my chain of evidence.

This portion of the work is far from complete, as I am only too well aware, but my facilities for bacteriological work are of the most meagre description.

CONCLUSIONS.

(1) From an intensive study of films from over sixty cases of clinical cholera there is no evidence that the comma bacillus plays any part in its causation in Cachar.

(2) This may be due to there being two varieties of clinical cholera, but should this be the explanation (and I rather incline to another view), Cachar and Bengal are so close geographically, and so alike climatically, that a disease of similar ætiology will almost certainly account for a large number of cases of clinical cholera in Bengal.

(3) On the evidence of films, clinical cholera in Cachar would appear to be associated with a small cocco-bacillus which often assumes a bi-polar staining form. Whether this is identical with the small spore-bearing bacillus is not yet certain.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

(4) The other organisms present—spirochætes, etc.—are not constant, and probably represent secondary growths in rice water fluid of organisms which find conditions suitable for their rapid growth.

(5) Clinical cholera in Cachar has been found associated with infection presumably due to pig's fæces.

(*Note.*—We publish Colonel Palmer's article, chiefly because of its epidemiological interest, though we dissociate ourselves entirely from his view of the bacteriology of cholera. Cholera-like conditions may be due to many causes—to malignant tertian malaria, to name but one.—EDITOR, *I.M.G.*).

A Mirror of Hospital Practice.

A CASE OF DERMATOLYSIS.

By M. UMAR,
Bijnor, United Provinces.

THE patient, Allah Dai, Mahommedan female, aged 22 years, married, was admitted to this hospital for treatment of the condition shown in the accompanying photographs.

History.—Her mother states that when Allah Dai was born, the child's left leg was bigger than the right. She was married at the age of 18, and became pregnant 2 years later. In the 7th month of her pregnancy,

Fig. 1.

pain began in her left leg. This increased daily and the leg commenced to enlarge. She gave birth to a stillborn child. From that date the pain and swelling have increased more rapidly.

Condition on admission.—The whole of the muscles and subcutaneous tissues concerned in the thighs and gluteal areas are so loose that they hang in folds about the body. The labium majorum on the left side is enlarged to

Fig. 2.

such an extent as to push the vaginal orifice to the right side, and the latter can only be recognised as a cleft by the presence of hair. For the past 5 months the patient has not menstruated. There is no history of syphilis.

The patient refused to stay in hospital.

Discussion.—In my opinion there is no treatment possible for this condition. It is one of the malformations which increase after puberty is attained. If any reader of the *Gazette* can suggest a correct diagnosis and the best line of treatment for the condition, I shall be grateful.

(*Note.*—We have shown the above notes and photographs to Lieut.-Col. H. W. Acton, I.M.S., who is in charge of the skin out-patient department of the Calcutta School of Tropical Medicine. Colonel Acton remarks that the condition present is clearly one of dermatolysis. This is a rare condition, usually familial or of hereditary tendency, and the condition is slowly progressive once it appears, and especially so after puberty. It is apt to be mistaken for elephantiasis in this country. In 1926 two similar and very interesting cases were seen at the Calcutta School of Tropical Medicine, which affected mother and son, the latter especially with regard to the scalp. The condition is often associated with multiple small fibromata—von Recklinghausen's disease; and the second of the two photographs above appears to show such small fibromata present on the front of the right thigh of the patient.

There is no treatment for the condition, except excision, which is often impracticable.—EDITOR, *I.M.G.*).

COLLOIDAL DRUGS

Pharmasols REGD.

Pharmasols REGD

CALCIUM.

Composition—Colloidal Calcium Hydroxide in loose combination with organic Colloids.

Intravenously, Intramuscularly, Orally.

Pharmasol Calcium has a definite place in the treatment of **Tuberculous Enteritis;** cases of healed intestinal ulcers have been reported by repeated injections of **Pharmasol Calcium** in patients dying of **Pulmonary Tuberculosis.**

This method of treatment is advocated in **Tuberculosis** of the **Bones, Joint, Peritoneum and Kidney.**

PHARMASOL CALCIUM INJECTIONS.

For Adults.—The average dose is 1 c.c. every second day, intramuscularly or intravenously.

For Children.—The dose is 0·1 c.c. gradually increasing.

ORAL TREATMENT.

Oral administration in addition to injections, has been peculiarly successful in reducing sputum and getting rid of tubercle bacilli from the sputum. **Pharmasol Calcium** oral may be combined with the injection treatment or given separately.

DOCTORS

Beware of Dangerous and Fraudulent Imitations.

Read this carefully. *Times of India.*

SKILFUL IMITATION OF PRODUCTS.

FRAUD ON CHEMICAL FIRMS.

Special to "Times of India."

PARIS, (By Mail).

So cleverly did a gang of fraudulent patents medicine vendors make up and sell quantities of faked medicines to chemists in Paris and elsewhere in France that the proprietors of the patent medicines themselves when asked by the police were unable to distinguish their own products from the faked ones. The bottles, labels, printing and wrappings were all exactly imitated. Large shipments were made to Cuba and Mexico by deluded purchasers of the counterfeit medicines. Several arrests have been made but the police do not yet believe that they have caught all the men involved in the fraud which has cost reputable houses many thousands of pounds.

One of the cheated chemists with the connivance of the police set up a temporary export bureau and gave an order to the suspected persons. They duly delivered the falsified goods only to find themselves on arrival in the hands of the police.—British United Press.

SULFARSENOL AND ONLY GENUINE PACKING FOR INDIA

Imitations of SULFARSENOL of inferior quality have been put on the market by unscrupulous and cheap firms.

Beware—These fraudulent substitutes are no good for India. They do not keep fresh, they loose their activity and become dangerous toxic drugs.

For a few annas it may be a question of LIFE or DEATH for your patient. YOU may lose YOUR REPUTATION and PRESTIGE.

Insist on the only Genuine Package—it is in your own interest.

Note the only Genuine Package of

SULFARSENOL

Specially prepared for India and carrying the FULL GUARANTEE OF THE MANUFACTURERS.

If your chemist cannot supply the genuine SULFARSENOL, write to the

INDO-FRENCH DRUG Co.,

P. O. Box 458, BOMBAY.

Warning.

Genuine SULFARSENOL in the genuine packing is the only product passed by the Medical Research Committee and no other will be replaced in case of complaint.

BENZO BISMUTH

A. F. D.

Benzo-Bismuth is a stable organic bismuthic salt *entirely soluble in water* for the treatment of *Syphilis* giving remarkable results.

(2) Ease of administration—Small quantity injected (maximum dose 1·5 c.c.) either *intramuscularly* or *subcutaneously*. No disadvantages of disagreeable oily suspensions of Bi & Hg.

(3) Complete absence of Bismuth poisoning and unpleasant local symptoms. *Painless and non-toxic.*

(4) Benzo-Bismuth is supplied in boxes of 5 ampoules of the salt and 5 ampoules of distilled water ready for immediate use.

Price Rs. **4** per box.

GONORRHOEA

Pharmasols REG.

PALLAMINE

Composition—Colloidal Palladium metal.

Intravenously, Intramuscularly, Orally.

Acute Gonorrhœa, Gonorrhœal Metritis. Cuts short the course of the disease after the first few injections.

In boxes of 6 ampoules (0·05%) of 1 c.c. Rs. **3-8**

Oral—(0·05%) in bottles containing 4 oz. Rs. **3-8**

In bottles containing 1 oz. (for injection) Rs. **4-0**

BLENACROL

A.F.D.

Blenacrol A. F. D. is twenty times as powerful as mercury subchloride and 800 times as active as **Phenol**; a solution of **Blenacrol** 1|200000 will prevent the development of the cultures of gonococci, where the **Protargol** universally used has no effect on these same cultures, even when at a strength of 1|500. **The bactericidal action of Blenacrol A. F. D. is therefore 400 times more powerful than that of Protargol** and it is therefore the ideal remedy, in all forms of **Gonorrhœa.**

Blenacrol A. F. D. to be used for douching in the proportion of 1 to 2 table-spoonfuls per pint of sterilised water.

In bottles containing about 3 ounces Rs. **4-0**

Indian Medical Gazette.

APRIL.

PREVENTABLE YET NOT PREVENTED.

It is easy to point with pride to the triumphs of medical science. In England and other European countries the average duration of life has been greatly increased within the past fifty years. Many diseases have been banished from Western Europe, for example plague, cholera, leprosy, typhus fever and relapsing fever. Small-pox would have vanished long ago but for the apparent desire of certain people to retain the disease in our midst.

Altogether the improvement in our conditions of life have been such that nobody would care for a return of the "good old days." But there is another side to the picture, we have some conspicuous failures to record. Diphtheria is as common as ever, though it is not so fatal owing to the use of antitoxin; rheumatic disease of the heart shows no sign of disappearing; cancer and insanity are definitely on the increase.

It is advisable to look closely into these diseases which have not been controlled by modern medicine and to enquire whether there is no possibility of causing a diminution in their ravages.

Insanity and mental defects are often due to inherited defects, and there is little prospect of controlling them unless we are prepared to prevent the propagation of the unfit. Public opinion is not prepared for legislation for the sterilisation of the mentally defective, so that the only means of dealing with this problem is by propaganda for the instruction of the public in the danger of transmitting inheritable disease.

Rheumatic fever offers better hope of successful action. The experts advise us to adopt early diagnosis and treatment as the most promising methods of control, but prevention is hardly mentioned as a possibility.

There is a good deal of evidence that the rheumatic infection enters the body by the tonsils and upper air passages: if this be so the disease must be classed with the droplet infections and dealt with accordingly.

It is remarkable that those very persons who insist that the infection enters by the respiratory passages are also those who advocate early diagnosis as the best method of alleviating the damage which is done by rheumatic disease of the heart. Medical men seem to suffer from a peculiar form of inhibition in the case of droplet infection, they repeat the formula that respiratory infections are conveyed by droplets of sputum and we expect them to carry their belief to its logical conclusion, but to our surprise they shy off as if it were impious to interfere with the efforts of nature to perpetuate the bacteria which make their homes in our air passages. It would appear that there is a lack of faith in the doctrine of droplet infection in connection with rheumatic heart disease and we do not care to interfere with the habits of the community unless we have a definite assurance that our efforts will be successful.

But suppose that we were to start a compaign against the spread of droplet infection, holding out as a bait the hope that heart disease might be controlled. Suppose then that we were to succeed in reducing air-borne infection to the same extent as we have reduced water-borne infection. We might conceivably fail to control rheumatic heart disease but we should almost certainly have banished many other diseases which are conveyed by sputum spray, and it is likely that the public would take a lenient view of our failure to abolish heart disease, seeing that we had caused a great reduction in influenza, pneumonia, diphtheria, tonsillitis, bronchitis and tuberculosis.

We are filled with horror and disgust when we think of swallowing food and water which are contaminated with fæcal matter, but we have not the slightest objection to inhaling air which has been fouled with particles of sputum. It is decidedly unfair that water-borne bacteria should be pursued so ruthlessly while their air-borne brothers enjoy immunity from pursuit. Evidence has been brought forward that the air passages of the new born babe are exceptionally devoid of defence against respiratory infection, so that air-borne bacteria which lodge during the first few weeks of life are capable of installing themselves permanently. Whether this view is completely true or only partly true, it is obvious that we ought to take special precautions to keep infants free from the dangers of respiratory infection which they are compelled to run owing to the ignorance of their parents and attendants. The control of respiratory infections would be much easier in childhood than in adult life, and if we could cause a great reduction in the numbers of the carriers of bacteria of the air passages in childhood the problem of dealing with adults would be greatly simplified.

We have not learned the lesson of the pandemics and epidemics of influenza. Undoubtedly these were spread by droplet infection, yet we view with fatalistic inaction the march of influenza through families, offices and schools. We tolerate the people who cough and sneeze in churches, threatres and rooms; the mere idea of restraining them from spreading infection is repugnant to our sense of propriety. People have always been allowed to

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

cough and sneeze whenever and wherever they feel inclined to do so; this is one of the cherished rights of the citizen. The best that we can hope for is to carry out active propaganda in the hope that the next generation will grow up with less respect for the filthy customs of their ancestors and it may then become practicable to institute a campaign for uncontaminated air.

The pictures of Hogarth show that the citizens of London were in the habit of throwing filth of all kinds into the streets; we have progressed far since the 18th century, but we have still some way to go.

Cancer is definitely on the increase. In the case of this disease there is no need to arouse the community to a sense of their danger, everybody knows that those who have reached the age of thirty in England have a one in seven chance of dying of cancer. In India the risk is somewhat smaller, chiefly because the other causes of death are so energetic that cancer has to take a lower place in the list of the causes of death.

Sir Berkeley Moynihan recently addressed a large and poignantly interested audience in London on the subject of cancer. He pointed out that many of the theories of the causation of that disease had little or no evidence to support them. Heredity, diet, infection, contagion, locality cannot be demonstrated to play important parts. On the other hand he rightly emphasised the fact that chronic irritation is often a precursor of cancer, he gave as examples cancer of the tongue, mule spinner's cancer and the *kangri* cancer of Kashmir. Many other examples could have been cited, as we have already pointed out more than once in these pages.

Sir Berkeley's advice to the public was on the same lines as that given by the recent International Cancer Conference, he advocated propaganda for the instruction of the public in the early manifestations of the disease so that it may be diagnosed at a time when surgical treatment can be carried out with hope of success. This advice is good, but it offers cold comfort to the millions who live in dread of the disease, and it fails to help those who suffer from deep-seated cancer. It is somewhat surprising that neither Sir Berkeley nor the International Cancer Conference have followed up the one definite clue which we possess to the causation of the disease. There are at least a dozen forms of cancer which are known to follow chronic irritation. In the case of these we can definitely assert that the disease can be avoided by eliminating these forms of irritation. It does not matter in the least that there may be other factors concerned, the important thing is that there is one known factor which is essential to the causation of cancer in certain cases, for example the *kangri* cancer, mule spinner's cancer, radiographer's cancer, and betel chewer's cancer. If chronic irritation is proved guilty in some forms of the disease, it is also under strong suspicion in the case of others. It is significant that cancer of the penis is common among Hindus and rare among Mahomedans. The obvious difference between these two sects is that the one adopts circumcision and so avoids the possibility of retention of irritating smegma between the foreskin and the glans penis, while the other lays itself open to this danger. It is therefore clear that circumcision or even cleanliness of the penis will prevent many cases of cancer. There is plenty of evidence that cancer of the œsophagus and stomach is much more common in Europe than in India. We cannot find an explanation in racial differences of susceptibility as we know that some other forms of cancer are more common in India than in Europe. As chronic irritation has been convicted of responsibility for certain kinds of cancer, we naturally ask whether it may not be concerned in this difference in incidence of cancer of the stomach and at once we find a possible explanation of the frequency of the disease in Europeans when we consider the extent to which the drinking of scalding hot liquids prevails in the colder countries. Prolonged irritation by heat has been proved to be the cause of *kangri* cancer and it is reasonable to expect that the delicate mucosa of the œsophagus and stomach will suffer readily by frequent applications of hot liquids. This clue is well worth following up, especially as there is no possible danger in advising people to give up a habit which can do no possible good but may be exceedingly dangerous. It would seem to be worth while to lay stress on such a possibility as this, even if we have no absolute proof that we can abolish cancer of the stomach by so simple a means.

The cervix of the uterus is obviously much exposed to chronic irritation, but this is a subject on which the gynæcologist is best qualified to express an opinion. The rectum is another organ which is exposed to irritation associated with constipation. The breast is one of the favourite seats of cancer, and though it is perhaps more difficult to suggest a clear association between chronic irritation and cancer of the breast than in the case of the other organs, there are many examples on record in which there is a strong suggestion that irritation is an important factor. The position then is that we can dogmatically assert that some forms of cancer can be prevented with certainty, there are others in which we have valuable clues to prevention, and there are comparatively few in which we cannot find any evidence of a helpful nature.

There is no need to spoil our case by making dogmatic assertions which are not supported by known facts, but there is no reason

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

why we should not state clearly the facts which are in our possession and the inferences which may reasonably be drawn from them. So long as we make it clear that we are dealing with very suggestive clues—not with proved certainties—there is no danger of unpleasant recriminations afterwards. Further research should be carried out with renewed energy, but some of the research workers should be set to work to follow up the definite clue which we possess in connection with chronic irritation.

The knowledge which we already possess is of so suggestive a nature that we are amply justified in advocating an avoidance of the forms of irritation to which certain organs of our bodies are subjected. At present our action resembles that of the leper in the Scriptures who refused to wash in the waters of Jordan because he had no evidence that these had any properties different from those of the rivers of his own country. We also are inclined to regard the discovery of the cause of a disease as an end in itself, rather than as a means whereby prevention and treatment can be improved. If we were to prevent certain forms of cancer merely by following up a suggestive clue, the delay in finding out the ultimate secrets of cancer causation would be less of a tragedy. In everyday life the business man takes action on more slender information than we possess in the case of cancer. The verdict of future generations may well be that we have failed, not so much in acquiring knowledge, as in refusing to act on the knowledge which we have already accumulated.

We make no apology for returning to a subject which has already been dealt with more than once in this journal, its importance is a sufficient justification for the action. No claim is made for originality in the views which have been expressed as to the part played either by droplet infection or chronic irritation, but we do claim that rational lines of action for the control of these uncontrolled diseases have never been clearly advocated or emphasised.

Just after writing these lines an interesting book review has reached us. This appears in the *British Medical Journal* of February 5th, 1927: it refers to a volume by Dr. Menetier of Paris on cancer. Twenty years ago Dr. Menetier held that cancer is secondary to multiple and non-specific irritative processes. He still adheres to the same view in spite of all the special research which has been carried out. The volume has not yet reached India, but the reviewer does not mention that Dr. Menetier advocates the avoidance of these known forms of prolonged irritation.

If cancer is caused by prolonged irritation of organs, why allow the irritation to continue?

SPECIAL ARTICLE.

COMMENTS ON THE PRESENT POSITION OF THE TREATMENT OF LEPROSY.

By E. MUIR, M.D., F.R.C.S. (Edin.),

Leprosy Research Worker, Calcutta School of Tropical Medicine and Hygiene.

(The following is an article sent by Dr. Muir to Sir Leonard Rogers, who read it before the Tropical Diseases' Section of the Royal Society of Medicine on the 3rd February 1927. It is therefore likely that the paper will appear in the *Proceedings of the Royal Society of Tropical Medicine*. The subject is, however, of such importance in India that we have taken the liberty of publishing Dr. Muir's article; with due acknowledgments to our contemporary should the article appear in the *Proceedings of the Royal Society of Medicine*, 1927.—EDITOR, *I.M.G.*).

Introductory.

IT is necessary to emphasise that there is no specific for leprosy, i.e., there is no specific in the sense in which antimony is a specific for kala-azar or quinine for æstivo-autumnal malaria. It may also be clearly stated however that there is a line of treatment which will cause the permanent disappearance of all active signs of the disease in early cases so that the patient is for all practical purposes *cured*, though, if a marked reduction in his general health occurs later, there is always the possibility of a relapse.

It may be confidently asserted that if leprosy and tuberculosis be compared stage by stage, the former is the more remediable of the two diseases. Leprosy in almost all cases can be diagnosed with ease from clinical signs long before bacilli can be found in the lesions. Pulmonary tuberculosis can also be diagnosed in its earliest stage before bacilli can be found; but, speaking generally, the prognosis in such an early case of leprosy is more favourable than that in the corresponding case of tuberculosis.

Form of Treatment Recommended.

The following is the line of treatment used at present in Calcutta, the items being mentioned in the order of procedure:—

1. The treatment, when present, of accompanying diseases, both physical and mental.
2. The rectification of the diet.
3. Gradually increasing exercises.
4. The use of special drugs, the injection of hydnocarpus oil, and its preparations being the most important.
5. External applications and surgical interference when necessary.

It is beyond the scope of this paper to go into the full details of this treatment, but illustrations of the importance of its various items may be mentioned.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Syphilis is one of the most important of the diseases accompanying leprosy as we find it in India. We have frequently seen treatment carried on for lengthy periods in cases of leprosy in which the presence of syphilis had not been diagnosed, the patient only growing worse. In such cases the recognition and treatment of syphilis has been accompanied by immediate improvement, the leprosy sometimes clearing up without any special treatment beyond that of ordinary anti-syphilitic measures. Malaria, dysentery, and other diseases, which lower the resistance also frequently lay the patient open to leprosy or prevent his recovery.

As in tuberculosis, attention to diet is exceedingly important. A recent enquiry into the reasons for the very much higher endemicity of leprosy in some parts of India as compared with others has brought out the fact that the diet of the people is the most important factor. The better results obtained in the out-patient treatment of leprosy as compared with the treatment in asylums is largely due to this. In one of these institutions, where treatment is being carried on with indifferent results, the patients are given a supply of rice along with one and a half annas a day for their food. Those who buy good food with the money are in a constant state of semi-starvation, while others who buy cheaper food, such as the favourite badly preserved fish of that district, remain in a state of food intoxication. What wonder if the treatment is ineffective?

Gradually increasing exercises are no less important in leprosy than in tuberculosis, but the graduation does not need to be as slow or as carefully regulated as in the latter disease. This is another reason why out-patient is better than in-patient treatment, as in many of the asylums in India there is but little opportunity for exercise. This defect, however, is being rectified to a large extent in the best institutions, and in many of them patients have the chance of adding to their food supply by the labour of their own hands. Improvement is generally rapid in those who through well regulated exercises, games, etc., bring their bodies under training. Leprosy seldom makes the patients feel ill or confines them to bed, except those who have reached the deformities of the last stage; and thus from the nature of the disease such physical development is possible. On the other hand, the rapid progress of leprosy from bad to worse when it occurs, is often largely due to the despair and physical and mental inertia which are induced by fear and horror in the patient who knows that he is suffering from this much dreaded disease.

Case 35.
Before Treatment.

Case 35.
After Treatment.

With regard to the special drugs used, we have found, after much testing of various vaccines and other remedies which have been recommended, that chaulmoogra and hydnocarpus oils and their derivatives stand in the first place.

It is not easy to test drugs in a reliable way in leprosy. From the very nature of the disease mistakes are apt to be made. One of the commonest of these errors is caused by

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the reactions which often occur. The disease may follow a quiet course, the bacilli multiply in the skin, lymphatics and nerves, until suddenly, due to one of a hundred possible causes, the phase of reaction intervenes. Lesions which had not been noticed before, or had been ignored as of no importance, become suddenly red and swollen and the patient seeks the advice of the doctor, who experiments with some drug or other and finds to his delight that in a short time the lesions subside. He does not realise that the erythema and swelling of the lesions indicate only a phase in a process which had been going on unnoticed for years, and that in the natural course of the disease they would have subsided of their own accord; and he accordingly gives the credit for the apparent improvement to whatever remedy he may have happened to use. Most of these remedies, which are heard of from time to time, have been tested on only a few cases or even on only one case. Certain drugs do, however, possess a marked power in reducing leprous reactions when these do not pass off of themselves within a short time; and such remedies are of special value as prolonged reactions weaken the patient considerably and may cause the formation of new lesions and a rapid extension of existing ones, especially in the earlier stages of bacteriologically positive cases. Among such reaction-reducing drugs we have found antimony the most useful, and have frequently proved that a few intravenous injections of small doses (0.02 to 0.04 grammes) of potassium antimony tartrate rapidly bring about a cessation of active signs which had persisted for several weeks.

The treatment of the actual disease in its prolonged course must, however, be distinguished from the treatment of such reactions which come and go, and for this purpose we have found that, though vaccines are useful—especially in certain cases, hydnocarpus oil and its derivatives are the most reliable standard treatment.

Our present routine is to begin with injections of hydnocarpus oil containing 4 per cent. creosote given either intramuscularly or by infiltration under the skin of the extensor surfaces of the body. Injections are given twice a week, beginning with 4 c.c. and gradually rising to 10 c.c. When patients are able to stand the latter dose without local or focal reactions, a solution of sodium hydnocarpate in saline 1 per cent. is given intravenously twice weekly, beginning with 2 to 4 c.c. and rising to 10 c.c. These are continued until either a reaction is produced or the veins become blocked, when oil infiltration is substituted once more. The veins become blocked by sodium hydnocarpate in some cases but not in others. We have not yet been able to discover what causes the difference between patients in this respect. Probably an alternation of these two methods is the best way to administer hydnocarpus treatment. The oil given subcutaneously or intramuscularly is more slowly absorbed and less likely to cause reactions. The sodium salt in watery solution, being more quickly absorbed, has a greater tendency to cause reactions.

It may be asked whether we should aim at causing reactions in carrying out the treatment and what are the advantages and dangers connected therewith.

Case 59.
Before Treatment.

Case 59.
After Treatment.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

In the earliest cases, which can only be diagnosed clinically, seeing that bacteriological examination is negative, there is not sufficient lepromatous tissue in the body to break down and cause a reaction. Later on, when there is a greater number of lepra cells and yet not a high degree of immunity, a reaction, accompanied as it is by the setting free of bacilli in the blood stream, often results in the metastatic formation of new lesions. Still later, however, a third stage is reached in which a reaction is followed by beneficial results. The lepromatous tissue breaks down, and bacilli are carried to different parts of the body; but at this stage sufficient immunity has been acquired to cause their destruction; and, though small nodules appear in the skin at various points indicating the blocking of capillaries with bacillary emboli, they soon disappear again and leave no trace. In the fourth stage, in which bacilli have again become reduced in number and those that remain are more confined to the nerve trunks, the stage in which anæsthetic lesions and deformities appear, reactions may occur in the nerves and cause considerable pain.

It is in the second stage, however, that particular care has to be taken to avoid untoward results. Only very small doses of hydnocarpus oil or its preparations should be given until the general resistance of the patient has been improved by carrying out treatment

Case 133.
Before Treatment.

Case 133.
After Treatment.

Digitized by Arya Samaj Foundation Chennai and eGangotri

along the lines first mentioned, and especially until his muscles have become hardened by exercise: thereafter comparatively large doses may be administered without fear of reaction. In the third stage treatment may be pressed without fear of extension or exacerbation of lesions. Moreover in this stage benefit may be caused by innumerable forms of treatment. In such a patient there is sufficient immunity to cause destruction of all the bacilli in the body; but the organisms, being protected by their position in the lepra cells, remain undestroyed. Anything, therefore, which leads to the breaking down of these cells causes improvement.

Among the agents which break down lepra cells may be mentioned the following:—(a) acute fevers such as malaria, kala-azar, streptococcal and staphylococcal infections; (b) anything which causes protein shock; and (c) the injection of irritating substances such as many of the drugs which have been used in leprosy with beneficial results. In one most striking case acute *exfoliative dermatitis* was caused by administering stovarsal. The patient almost lost his life, but on his recovery the bacillary infection, which had been a very marked one, had almost entirely disappeared, only a few granular remains of bacilli being found upon bacteriological examination. This case was particularly instructive as showing how rapidly lepra bacilli can be cleared out of the skin in certain circumstances.

In patients in the third stage vaccines are very useful, especially when given intravenously, but the action is more of the nature of anaphylactic shock than specific.

The real test of the efficacy of any special treatment for leprosy is its effect in the first and second stages; and we find in Calcutta that hydnocarpus oil and its preparations are the most useful special remedies in these stages.

Leprosy as a rule is not a very painful disease except when nerve reactions take place. These may however be very severe and cause great distress. One or more nerve trunks become swollen and so tender that the patient cannot bear the lightest pressure on them or the slighest movement of the parts affected. Sometimes only one nerve is affected: at other times several; when limited to one nerve its swelling and tenderness are relatively more marked. The intramuscular injection of 3 or 4 minims of 1 in 1000 adrenalin chloride diluted with 30 minims of normal saline has often an almost magical effect in causing cessation of pain, especially when several nerves are affected. If the reaction is confined to one or two superficial nerves, infiltration of the connective tissue round and outside their sheaths with 0.5 per cent. sodium bicarbonate solution in distilled water generally gives rapid relief. In a few cases, however, when the swelling is very rapid and severe, these measures only partially allay the pain, and in these cases it is advisable to cut down along the line of the nerve and free the nerve trunk, which may be 1|3rd or even ½ inch in diameter from the surrounding tissues. The nerve most frequently affected is the ulnar, which when much swollen may be constricted between the humerus and the fascia which passes

Case 110.
Before Treatment.

Case 110.
After Treatment.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

from the internal condyle to the olecranon. The severing of this fascia often has a very beneficial effect, and may save the patient from rapid trophic changes in the small muscles of the hand. The freeing of the nerve is followed by instant relief from pain and diminution of anæsthesia in the zone of ulnar distribution: within a few hours of the operation the fingers can be moved much more freely.

It is not within the scope of this paper to go into further details of treatment but I think that enough has been said above to make the following points clear:—

1. That, if treatment is to be effective, it must follow the careful study of each individual case; and that rule-of-thumb remedies are not likely to give good results.

2. That any line of treatment which does not put the restoration and maintenance of the general health and resistance of the patient in the forefront will seldom succeed.

3. That permanent lesions must be clearly differentiated from those caused by bacillary infection present at the time; otherwise confusion and disappointment may arise.

LENGTH OF TREATMENT.

How long should treatment be continued?

Generally speaking, till all active signs have remained absent for a period varying from 6 months to 2 years. It is certain that the disappearance of active signs does not correspond with entire disappearance of disease. What then is to be the guide as to how long treatment should continue after active signs have vanished? If the progress up to that point has been rapid, it stands to reason that the progress after that point will probably be equally rapid and therefore post-active-sign treatment may be curtailed. If on the other hand progress up to the disappearance of the active signs has been slow, treatment must be continued thereafter for a much longer time.

What should be considered the criterion of the disappearance of all active signs?

(1) Inability of an expert to find upon careful, repeated examinations of the skin by clip smears, of the nasal mucosa by scraping, of the lymph nodes by puncture, or in any other way possible, any traces of Hansen's bacillus over a period of 6 months. (2) The disappearance of all erythema from macules and the absence of all changes in lesions, such as the increase or decrease of anæsthesia, during a period of 6 months.

After this point is reached and special treatment has been stopped, the patient should always appear for inspection at stated intervals for at least 2 years. He must be warned that, although from a clinical point of view he is cured, there is no certainty that the infection has entirely disappeared from the body, and that anything which interferes with his general health may be followed by the reappearance of the disease; although the longer he continues free from active signs the less likely are they to recur.

Case 136.
Before Treatment.

Case 136.
After Treatment.

Causes of disappointment with treatment.

The permanent efficacy of antileprosy treatment has been doubted by many authorities. Failure to obtain good results is largely due to one or more of the following causes:—

1. Because leprosy is not recognised in its earlier stages and only advanced cases are treated, either those in which lepromatous infiltration has become generalised, the larger

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

part of the skin and the nasal, buccal and pharyngeal mucous membranes having become involved, or cases in which deformity has already begun to set in.

2. Because the treatment has consisted only of some special drug administered either orally or by injection, while there has not been recognition of the paramount importance of treatment of the general condition of the patient and restoration and maintenance of his general health, both during and after treatment. We should not think much of the skill or knowledge of a doctor who treated tuberculosis by a drug alone, and neglected diet, sunlight, open air, rest and graduated exercises, and the other generally approved elements in the treatment of that disease. Still, all these factors are equally important in the therapy of leprosy and success cannot be expected unless due emphasis is laid upon them.

3. Because it has not been realised that there is generally at the back of leprosy some other disease such as syphilis, malaria, etc., which is lowering the resistance of the body and which must be remedied first if improvement is to take place.

Case 153.

Digitized by Arya Samaj Foundation Chennai and eGangotri

4. Because the difference between permanent and active lesions has not been recognised. I have seen patients, in whom infection had been absent for years, being treated in the hope that sensation would be restored to anæsthetic limbs, and the treatment condemned because there was no improvement. The doctor did not recognise that anæsthesia was due to fibrosis of the nerve trunks and destruction of the axis cylinders of the sensory nerves, and that restoration of these nerves and of sensation was no more possible than the restoration of the fingers which had disappeared.

5. Because claims have been made for cures when all that had occurred was the subsidence of a reaction and the clinical signs that accompanied it.

Finally I should like to repeat that we have as yet no remedy which in the true sense of the word may be called a specific cure, any more than we have such a remedy in tuberculosis; but by carrying out treatment along the lines indicated above we can hope for a permanent disappearance of all active signs in almost all patients in whom the disease is recognised early. In the later stages, although much more prolonged treatment is necessary, very promising results are obtained and many have become entirely well and remained so for periods of several years.

If this last statement is recognised as true, a little consideration will show its extreme importance in dealing with the problem of leprosy in a country like India. Hitherto, the fear of leprosy and the shame attending its

Case 456.
Before Treatment.

Case 456.
After Treatment.

6. Because cures have been declared without sufficiently thorough bacteriological and clinical examinations continued over a long enough period.

The following table is extracted from a list of patients who have remained free from all signs of leprosy from 1 to 5 years. Had we a more efficient intelligence department to follow up such cases the number would probably have been four or five times as large:—

Length of time of freedom from active signs.

	Number.

5 years	1
	64

presence have acted as two of the most potent factors in preventing recovery by depressing the patient and by leading him to hide the disease as long as possible till it had passed the early, easily remedied stages. Now that there is hope of recovery, fear of leprosy drives patients to come for treatment in the earlier stages, and about 80 per cent. of the patients attending the leprosy clinic at the Calcutta School of Tropical Medicine belong to these stages. The treatment of these patients is cutting off to a large extent the bacillary reservoirs which would have served to infect the next generation. We may doubt whether a true specific for the treatment of leprosy will ever be found—I myself doubt it very much—but I think that we have already in our hands a line of treatment which will aid the rapid disappearance of leprosy from India and from the world, though delay is inevitable ow-

ing to the ignorance and backwardness of certain classes of the community. I believe however that the carrying out of this treatment and the social and hygienic reforms which it implies, backed up by the widespread fear of leprosy which exists, is likely to become an important agent in ameliorating the backward condition of these people.

The following are short notes on some cases of special interest. Photographs shewing the state of patients before and after treatment are attached.

Case No. 35.—S. M., aged about 40 years, third stage; predisposing cause, malarial fever (bed-ridden for 3 months); duration 6 years, Wassermann reaction negative; erythemateous patch first noticed on arm, then after 2 years similar patches appeared on cheeks and other parts.

Case No. 59.—A. L. N., aged about 19 years, third stage; predisposing cause, dyspepsia; duration 10 years; smear from skin clipped from an ear and nasal smear bacteriologically positive. Wassermann reaction negative. Depigmented patch on right forearm to begin with; after 4 years the patch began to spread and similar patches appeared on other parts. Then a year after this, the lobes of his ears and patches became thickened.

Case No. 110.—R. M., aged about 30 years, third stage. Predisposing causes syphilis and malaria; duration 8 years. Smear from skin clip and nose bacteriologically positive. Wassermann reaction strongly positive on 7th November, 1924. About 3 courses of sulfarsenol and 1 course of novarsenobillon with bismuth cream and mercury ointment inunction, Wassermann reaction negative on 9th October, 1925. It became positive again on 2nd February, 1926. After 2 further courses of novarsenobillon and mercury ointment inunction, Wassermann and Khan reactions still positive.

Case No. 135.—A. C. P., aged about 47 years, second stage. Predisposing cause, syphilis; duration 1 year. Smear from skin clip positive; nasal smear negative; after a year's treatment skin became negative bacteriologically. Wassermann reaction strongly positive, but became negative after a course of novarsenobillon with mercury ointment inunction. A small depigmented patch appeared on right arm, then after 8 months raised erythematous patches appeared almost all over the body. Patient showed much improvement during the course of antisyphilitic treatment.

Case No. 136.—S. H. G., aged about 24 years, second stage. Predisposing causes, scabies and dyspepsia; duration 3 years. On 24th February, 1925, skin clip taken from right cheek bacteriologically positive; on 18th December, 1925, erythematous patches disappeared and skin bacteriologically negative and sensation regained on the anæsthetic areas of the lower limbs. Wassermann reaction negative. Had several erythematous thickened patches with thickening of lobes of ears.

Case No. 153.—T. S., aged about 30 years, second stage. Predisposing cause, syphilis; duration 3 years. Skin positive bacteriologically, but nasal mucosa negative. Wassermann reaction negative. Erythematous patch on the back was noticed at first.

Case 502.
Before Treatment.

Case 502.
After Treatment.

Case No. 446.—I. K., third stage. Predisposing causes malarial fever and gonorrhœa; duration 6 years. Skin bacteriologically positive and nasal mucosa negative. Wassermann reaction negative. Nodules were first noticed on his forehead and subsequently on other parts.

Case No. 456.—A. A., aged about 14 years, second stage. Predisposing causes malarial fever and constipation. Duration 10 years. Clip of skin from lobe of right ear positive bacteriologically. Wassermann reaction negative. Erythematous patch on left cheek with thickening of lobes of ears and anæsthesia of lower parts of right leg.

Case No. 502.—K., aged about 13 years, second stage. Predisposing cause, malaria; duration 12 months. Smear from skin clip bacteriologically positive and nasal smear negative. Wassermann reaction negative. A small erythematous patch on her left cheek was noticed at first; subsequently she had similar patches on the right thigh and forearm.

Current Topics.

Discussion on Some Recent Developments in Our Knowledge of the Biliary Tract.

By EVARTS A GRAHAM, M.D.,

Professor of Surgery, Washington University School of Medicine; and Surgeon-in-Chief to Barnes and St. Louis Children's Hospitals, U. S. A.

(*British Med. Journ.*, October 16, 1926, p. 671).

DR. GRAHAM read the opening paper on the above subject at the last annual meeting of the British Medical Association. He began by stating that the known normal functions of the gall-bladder seem to be relatively insignificant—namely, the regulation of pressure in the biliary system and the concentration of bile by the absorption of water.

In 1918 observations were published by Dr. Graham which indicated that inflammatory changes in the liver were a constant accompaniment of cholecystitis. Later the microscopic examination of gall-bladders removed at operation convinced Dr. Graham that, since often more inflammatory change is found at the periphery than in the mucosa of the organ in what seemed to be the early and the less severe cases, too much emphasis had been placed by the pathologists upon the importance of mucosal infection in the pathogenesis of cholecystitis. Many cases of cholecystitis are due to a lymphatic spread from a hepatitis, some are doubtless due to hematogenous infections of the gall-bladder, and some are probably due to involvement of the mucosa first and are therefore contact infections.

The diagnosis of typical cases of cholecystitis, either with or without calculi, is usually easy by means of the clinical history and ordinary physical examination. But the conditions which give rise to the typical signs and symptoms are usually late effects of disease. It is desirable to have some means of recognizing the presence of disease before the late effects have occurred, and to have a means of recognizing the atypical and obscure cases.

The work of Abel and Rowntree, which showed that the chlorinated phenolphthaleins are excreted largely through the liver into the bile, offered the suggestion that if atoms of bromine or iodine should be substituted for chlorine a substance might then be at hand which would not only be excreted into the bile but would also render the gall-bladder opaque to the Roentgen ray.

In 1923 W. H. Cole and Dr. Graham, later in association with Copher and Moore, investigated this problem. Because of the high atomic weight of iodine the first substance which they used was tetraiodophenolphthalein, and they succeeded in demonstrating the fact that with this substance cholecystography is possible, at least in dogs. This substance is secreted almost entirely by the bile—approximately 98 per cent. as shown experimentally in the dog. Recently they found that phenoltetraiodophthalein not only produces good shadows of the gall-bladder, but also colours the serum sufficiently after alkalinization of it to make it possible to employ it as a test of hepatic function in a manner similar to the Rosenthal test with phenoltetrachlorphthalein. Therefore, this substance may be used simultaneously for cholecystography and for tests of hepatic function. It also colours the urine after alkalinization, but since only about 2 per cent. of it is secreted in the urine it will probably not be of much value as a test of renal function.

The densest shadows will be found in normal subjects, there may be no shadow at all, or only a faint one, if the liver is unable to excrete the substance normally if the cystic duct is occluded, or if the gall-bladder is unable to concentrate its contents because of a diseased wall. Moreover, as bile is poured out from the gall-bladder into the common duct, it is obvious that the shadow will diminish in size and gradually disappear entirely.

Cholecystography is really a means of studying the function of the gall-bladder rather than an indication of the exact pathological lesions present. This method of examination provides a means of determining the state of the only two functions of the gall-bladder known—namely, the regulation of pressure within the biliary tract, and the concentration of the contained bile.

The enthusiasm with which this procedure has been almost universally received has been astonishing. However, the method of administration of these substances which they proposed in their first publications has been considerably modified by later workers.

There are two serious objections to the oral method: one is the uncertainty of the amount of the substance absorbed, and the other that many toxic disturbances, such as diarrhœa and vomiting, occur. For these reasons, at the Barnes Hospital, the authors adhered rather closely to the intravenous method, almost as outlined in their early papers and as carried out in Great Britain by Cohen and Roberts with tetrabromphenolphthalein. Improvements in manufacture of the tetraiodophenolphthalein has resulted in their hands in an almost complete absence of toxic reactions after the intravenous administration. The use of the new isomeric compound, the sodium salt of phenoltetraiodophthalein, however, will almost completely obviate toxic reactions. In ninety-seven successive cases in which it was used intravenously there have been no severe reactions.

The authors' technique is thus described:—

For the adult of average size 3 or 3½ grams of the sodium salt of tetraiodophenolphthalein, or 2½ grams of the sodium salt of phenoltetraiodophthalein, are dissolved in from 30 to 50 c.cm. of water, filtered, and sterilized in a boiling water bath for fifteen minutes. The solution is slowly injected with a syringe in the morning between 8 and 9 o'clock, preferably in two equal doses, half an hour apart. Dividing the dose tends to eliminate any risk of a toxic reaction. If given very slowly, however, over a period of ten or fifteen minutes, in one dose there is but little danger of a reaction. Case has recommended the prompt injection of 0.5 c.cm. of adrenaline if any symptoms of a severe reaction occur, such as fall in blood pressure. They have found this helpful in the few cases in which it seemed necessary. Breakfast is omitted in order that the duodenum may be empty during the period of concentration in the gall-bladder. For lunch the patient may have a liquid diet, but it should contain little or no protein or fat. The evening meal may be taken as usual. They formerly employed large doses of sodium bicarbonate by mouth, lately, however, they have abandoned the use of the bicarbonate because it has seemed unnecessary. Roentgenograms are made four, eight, and twenty-four hours after the injection. Dr. Sherwood Moore, the director of the department of radiology, prefers not to use the Potter-Bucky diaphragm. A series of films is essential in order to gain information concerning the concentrating function and the changes in size of the gall-bladder.

An important modification of this procedure has been made by Miliken and Whitaker, who give a meal containing fat in order to determine the ability of the gall-bladder to reduce its size promptly.

Accuracy of interpretation depends very largely upon experience with the particular method of administration. Normally, after the intravenous method described above, a faint shadow of the gall-bladder will usually be visible in about four hours. At eight hours it will have increased in density and will often be somewhat smaller, probably because of reduction in volume by concentration. At twenty-four hours the shadow will usually be nearly or completely gone. If, however, no food at all has been taken since the injection the twenty-four-hour shadow may be the densest and smallest of all because of marked concentration.

The chief points in making the diagnosis of cholecystic disease are: (1) Failure to obtain a shadow when the technique has been properly carried out. They agree with Carman, in his statement based on a study

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

of 1,100 cases, that a failure to obtain a shadow is unexcelled in diagnostic value. (2) Filling defects. Soft calculi which are otherwise invisible frequently are seen in the cholecystograms as "negative" shadows, or filling defects. They occupy space in the gall-bladder which would otherwise be filled with the opaque substance. Many small stones often produce a mottled appearance which is very characteristic. (3) Irregularities of contour, denoting adhesions, diverticula, etc. (4) Variations from the normal in density of shadow, in the time of appearance and disappearance of the shadow. These last criteria are more difficult points to interpret than the former, and they constitute most of the failures in diagnosis. Other difficulties of interpretation have been encountered in certain cases of hepatic enlargement of unknown etiology.

Up to May, 1926, the authors examined at the Barnes Hospital 1,041 patients with tetraiodophenolphthalein and 103 with phenoltetraiodophthalein, a total of 1,144 patients with one or the other of the iodine compounds. In this series there were 128 operations at which the gall-bladder was removed and an opportunity provided for a microscopic examination of it. On this basis the operation confirmed the Roentgen-ray diagnosis in 124 cases.

They have had no alarming symptoms in any of the last 500 cases. The reactions have been headache, dizziness, slight nausea, weakness, nervousness, diarrhœa, vomiting, severe nausea, pain in back and abdomen, fever, "smothering," chills, and urticaria. The use of phenoltetraiodophthalein is accompanied by fewer reactions than tetraiodophenolphthalein.

Cholecystography, when properly performed, will give evidence of disease before it is recognizable by any method short of microscopic examination of the gall bladder, but diagnosis of normality in the presence of a clinical history and clinical findings suggestive of cholecystitis should be made with caution, and only after experience with the method.

Recently it has been possible to show that the gall-bladder can empty itself by calling into play only the two mechanisms of a gradual washing out by the inflow of fresh liver bile and of elastic recoil.

Sosman, Whitaker, and Edson have found that a meal containing egg-yolk and cream can reduce the cholecystographic shadow of the gall-bladder to about one-tenth of its former size within the brief time of one hour and forty-five minutes. Copher and Kodama have found that oleic acid is even more powerful in this respect.

Dr. Arthur F. Hurst, M.A., M.D. OXON., F.R.C.P., Physician to Guy's Hospital dealt with the Diagnosis and Treatment of Cholecystitis and the Prevention of Gall-stones.

Gall-stones are found in about 10 per cent. of the bodies of all people dying after the age of 20. Since in most, if not all, cases their formation is preceded by cholecystitis, and as cholecystitis is often not followed by cholelithiasis, the former must occur at some period in the lives of a considerable proportion of all adults. It is the most common of all abdominal diseases. In spite of this it is comparatively rarely diagnosed, largely owing to the fact that until quite recently textbooks of medicine gave most inadequate descriptions of the symptoms and diagnosis of the common mild form of chronic cholecystitis, attention being almost confined to the comparatively rare and consequently much less important suppurative and gangrenous forms of the disease.

Chronic dyspepsia, which does not quickly yield to treatment, calls loudly for the help of a diagnostic team, consisting of a clinician, a radiologist, and a pathologist, since it is only by the use of certain modern methods of investigation, which require special experience for their performance and for the interpretation of the result, that cholecystitis can be diagnosed with a considerable degree of certainty, and a scientific basis can be obtained for the rational treatment of each individual patient. The investigation should be sufficiently complete to decide whether any other conditions, such as a gastric or duodenal ulcer, chronic appendicitis, caecal and ascending colon stasis, and achlorhydria or hyperchlorhydria, are associated with it.

A carefully taken history should in most cases arouse suspicion when cholecystitis is present. Everybody should be familiar with Sir Berkeley Moynihan's classical description of the "inaugural symptoms of gall-stones," which are now recognized as the symptoms of cholecystitis, having no direct connexion with the presence of stones. The abdomen should, if possible, be examined at a time when the patient is actually suffering from discomfort; the gall-bladder itself is then always found to be tender. In this Dr. Hurst was surprised that Dr. Graham did not mention the chief use in the milder forms of cholecystitis, as distinct from gall-stones, of the wonderful new method of visualizing the gall-bladder which we owe to him—the palpation of the visualized gall-bladder under the *x*-ray screen. There are many cases of slight, non-surgical cholecystitis in which this is the only radiological sign of disease. He quite failed to confirm Rosenow's theory of the streptococcal origin from the teeth and tonsils of most cases of cholecystitis, as the infection is almost always due to pathological types of coliform bacilli, and streptococci have only been found in a single case.

The medical treatment of cholecystitis, in the stages in which the bile is infected but the wall of the gall bladder is either not infected at all or only superficially or slightly infected, often leads to complete recovery. Even in cases of gall-stones with infective cholangitis unless the symptoms are very urgent, a few days' preliminary medical treatment will often convert a very dangerous septic operation into a comparatively safe one.

The treatment consists in attempting to sterilize the biliary passages by very large doses of urotropine and in promoting biliary drainage. Dr. Knott has shown that the urotropine acts as a biliary antiseptic in spite of the alkalinity of the bile, although it is inactive in alkaline urine and alkaline serum. Consequently its action on the bile is not impaired when sufficiently large doses of alkalis are given to keep the urine premanently alkaline in order to prevent the bladder from being irritated by formalin, which is set free in acid urine. A mixture is prepared containing 100 grains of urotropine to the ounce, and another containing 1 drachm each of sodium bicarbonate and potassium citrate to the ounce. Half an ounce of the former and one ounce of the latter are given after breakfast, after tea, and after a tumbler of milk or water last thing at night. The dose of the urotropine mixture is increased by 1 drachm each day until the full dose of 100 grains of urotropine is taken three times a day. This can often be continued for many weeks without unpleasant symptoms; if any bladder irritation occurs, the dose of urotropine is temporarily reduced, and, if the urine is found to be occasionally acid, more alkali is added to the second mixture. Dr. Knott has recovered urotropine from the bile obtained through a duodenal tube, and in several patients has actually demonstrated the sterilization of infected bile. In most cases he has also given the patient a course of vaccine made from the organism isolated from the bile.

Biliary drainage is promoted by giving magnesium sulphate in concentrated solution one hour before breakfast, in just sufficient quantity to get the bowels satisfactorily opened without the use of any other aperient. Dr. J. F. Venables, has demonstrated that magnesium sulphate given in this way produces just as good a flow of bile as when it is introduced direct into the duodenum, so that the unpleasant method of non-surgical biliary drainage recommended by Lyon, in which a duodenal tube is passed every day, is quite unnecessary.

When achlorhydria is present one drachm or more of dilute hydrochloric acid should be given in about five ounces of sweetened water, to which the juice and pulp of an orange may be added, half an hour before breakfast, to help to sterilize the stomach and duodenum, and, with the addition of pepsin, as a beverage with

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

lunch and dinner, in order to make gastric digestion possible. When hyperchlorhydria is present the pain, which is then often very similar to that of duodenal ulcer, can generally be relieved by taking half an ounce of olive oil before meals. This has the additional advantage of causing a flow of bile by a similar reflex to that produced by magnesium sulphate.

GENERAL DISCUSSION.

Dr. F. A. Knott (London) said that during the past three years he had made with Dr. J. F. Venables, slightly over three hundred examinations of specimens obtained by the Einhorn tube.

Dr. C. F. W. Illingworth (Edinburgh) had kept accurate records of 132 cases. The intravenous method was used, 4 or 5½ grams of sodium tetraiodophenolphthalein being injected. Recently he had introduced a slight modification.

A few hours before the injection a large dose of magnesium sulphate was given, with the object of securing a partial emptying of the gall-bladder and ducts, which were then refilled by the fresh dye-laden bile from the liver. Only once had any alarming sequel occurred. In this case there was a rather serious collapse before half the fluid had been injected, the collapse persisting for nearly half an hour. A rigor occurred once, but it was transitory and passed off without later ill effect. One patient had a severe headache and one complained of tingling in the limbs. Of the remainder, 61 per cent. suffered no discomfort; the others had varying degrees of nausea or vomiting, never alarming, and invariably passing off in a few hours.

In 111 cases Professor Wilkie had carefully examined the gall-bladder at the operation. Dr. Illingworth had classified this series in various groups to illustrate the value of the test.

Group 1.—In 39 cases no gall-bladder shadow was present in the *x*-ray film (which was usually taken twelve to fifteen hours after the injection). Of these patients, 35 were found to present gross disease of the gall-bladder or ducts, stones, neoplasm, or well-marked cholecystitis, thus confirming the *x*-ray diagnosis. In the remaining four cases the gall-bladder and ducts appeared quite healthy. The reason for this discrepancy was to be found, perhaps, in their technique. In these cases radiograms were taken at one period only, some twelve or fifteen hours after the injection. If a whole series of exposures had been made at varying intervals after the injection a correct diagnosis might have been made.

Group 2.—This group included 53 cases in which a gall-bladder shadow of apparently normal appearance was obtained. The result of this group were rather less satisfactory. In 45 the diagnosis was confirmed, the gall-bladder being healthy. In the remaining 8, however, the investigation was misleading. One gall-bladder contained stones, few in number and too small to be visible on the *x*-ray film. In 4 a slight degree of cholecystitis was visible to the naked eye. The remaining 3 cases were of particular interest. At operation the gall-bladders were of fairly healthy appearance and no stones were present. The clinical histories had, however, been very typical, and it was thought advisable to carry out a bacteriological examination of the bile and the gall-bladder wall. In all 3 cases culture of one or both tissues gave a growth of a virulent diplostreptococci.

Group 3.—This group was a smaller one and required little description. It included those 8 cases where gall-stones were visible within the shadow of the gall-bladder. It was a point worth mentioning that the concentration of the dye around the stones might be of value as an index of the condition of the gall-bladder wall and as a guide to operative treatment.

Group 4.—In 9 cases the cholecystogram was poor and ill-defined, and in these cases gross disease of the gall-bladder was found to account for the appearance. Reliance could only be placed on the density of the gall-bladder shadow as an index of its functional capacity if the radiogram was a good one; in very stout patients this might be difficult to obtain.

Group 5.—There was only one case in this group. The cholecystogram showed a well marked hour-glass deformity, which was found later to be due to a very localized induration of the gall-bladder wall.

Group 6.—In patients suffering from obstructive jaundice the investigation had proved of no value. Whether the obstruction was complete or partial, the amount of dye excreted by the liver was insufficient to produce a shadow.

Group 7.—The last group included those cases in which a palpable swelling was present in the upper abdomen. In these cases cholecystography had proved of great value. The position of the lump in relation to the gall-bladder could be accurately defined and the differential diagnosis was thereby narrowed down. Their series included 5 such cases, and in each the investigation had been of real value. One patient, previously operated upon for an endothelioma in the thigh, developed a swinging temperature and a palpable swelling in the right upper quadrant of the abdomen. Cholecystography revealed a well defined gall-bladder shadow below the level of the lump; a diagnosis was made of secondary metastasis in the liver, and the patient was saved a further operation. In another patient a large epigastric swelling was similarly diagnosed as situated above the gall-bladder, and was found to be a large hydatid cyst in the liver. In a third patient the gall-bladder was seen flattened and compressed upwards by a tumour which proved to be in the transverse colon. The fourth case was similar, the gall-bladder being compressed upwards by a growth in the colon. In the last case a hydronephrosis was responsible for displacing the gall-bladder and also rotating it into a horizontal position.

Their conclusions were that cholecystography was of distinct practical value. The absence of a gall-bladder shadow was strong evidence of gross disease. A good shadow excluded gross disease, but could not be expected to give evidence of minor pathological changes. In jaundiced patients the investigation was of no value, though in their experience it was devoid of risk. Lastly, cholecystography was of considerable assistance in the differential diagnosis of abdominal tumours.

Dr. T. Izod Bennett (London) employed the oral method almost exclusively; not from fear of toxic general symptoms so much as from the risk of occasional venous thrombosis following slight extravasations. The difficulties of the oral method were purely those of obtaining a capsule which would be dissolved in the intestine after passing the pylorus unchanged. His last fifty cases had been almost uniformly successful, nor had general toxic symptoms ever been grave. In the absence of stone and gross infection, cases of gall-bladder disease did exceedingly well with medical treatment.

The important dietetic principles in biliary tract disorders were: (1) to give a diet of carbohydrates and vegetables which would improve bowel evacuation and throw a minimal strain on the liver, and which would also combat tendencies to obesity; (2) to give water in abundance; and (3) to utilize such foods as would promote biliary drainage. Natural waters with a rather large salt content were usually better than purer waters; normal saline was, he believed, an excellent drink for these patients. The food which most readily provoked emptying of the gall-bladder was egg-yolk, and he was trying the effect of giving beaten raw egg-yolk to his patients daily. As to drug treatment, he was convinced that magnesium sulphate in solution, taken on waking when the stomach was quite empty, was very useful.

Bile salts and urotropine were the other drugs which were useful, and these he prescribed in full doses. His experience was that by these methods most satisfactory results could be obtained in a very considerable proportion of cases.

Dr. J. H. Anderson (Ruthin) uses the oral method almost exclusively, salol coated pills. The intravenous

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

was perhaps more accurate as the dye was more under control; but the oral method was sufficiently accurate for routine use, besides having certain definite advantages. The possibility of pills remaining unabsorbed or being vomited was checked by a screening of the abdomen and radiological examination of any vomit. The dyes used had been the sodium salt of tetrabromphenolphthalein and tetraiodophenolphthalein prepared by Malincrodt of St. Louis, and in a few cases the sodium salt of tetraiodophenolphthalein prepared by Martindale of London; in all cases solutions were prepared a few hours before use and pills not more than ten days. Ill effects had been insufficient to cause any alarm, and in 20 per cent. of cases there was no reaction at all. In the oral cases the unfavourable sequels were limited to nausea, vomiting, and diarrhœa. Nausea was transient as a rule, but had once lasted for ten hours in a case where the gall-bladder did not fill, and where three stones were found at operation. Vomiting was never severe and never exceeded three times. The largest vomit was in a case where the dye had been dissolved in 60 c.cm. of water.

The Madras Medical Register.

THE Madras Medical Register is a publication which will be of interest to many of our readers. It contains a warning notice with regard to forms of professional misconduct, notes on medical registration in Madras, the text of the Madras Medical Registration Act, 1914, and a complete list of all registered medical practitioners in the Province, with their qualifications, date of registration and professional address. It is published annually by the Superintendent, Government Branch Press, Madras, at a cost of Re. 1, and is obtainable from the official agents for the sale of Madras Government publications, including the Superintendent, Diocesan Press, Vepery, Madras; Messrs. Thacker, Spink and Co., Calcutta; Messrs. Thacker and Co., Bombay; and the Burma Book Club, Rangoon.

Indigenous Systems of Medicine.

WE welcome most cordially the appearance of a small brochure by Dr. W. Burridge of King George's Medical College, Lucknow, on *Indigenous Systems of Medicine and Medical Science.** Dr. Burridge is an uncompromising realist, and he writes concisely, forcibly, and in admirable literary style; he has no use for attempts to make unscientific medicine pseudo-scientific, for it cannot be done; nor for attempts to degrade modern scientific medicine of to-day into a far inferior imitation of itself. In these days when every cult from that of herbalist to that of Ayurved clamours for State aid, it is time that someone should set down the truth honestly and without compromise, and that Dr. Burridge has done.

"Among the many things at present in unrest in India," he writes, "are the indigenous systems of medicine. Their foundations of anatomy and physiology are now known even to their chief admirers not to be of the nature of firm solid masonry, as once supposed, but instead to be almost entirely of the speculative or imaginary type. Reluctant, however, to face the implications of imaginary foundations, these admirers would now turn to 'research' in the hope of finding the superstructure of much more solid worth, and with that end in view Ayurvedic and Unani research institutes have been or are being built, chiefly at the taxpayer's expense.

"The object of the present work is to point out that orthodox medical practice in Europe was for many centuries a combination of the systems termed indigenous in India to-day, that the imaginary nature of their foundations was discovered several centuries ago, and that perturbed opinion thereafter turned to the superstructure, which research next showed to be as bad as the foundations. So long as facts are treated as facts, research on these indigenous systems in India can only give the results already obtained in Europe, and it would seem a waste of effort, time, and money to do the work again.

"An endeavour has also been made to indicate the tremendous gap between scientific medicine and medical systems."

Turning to the main subject matter of the book, Dr. Burridge traces the evolution of the mediæval English practitioner from classical and ancient medical systems. Someone—Sir Arthur Keith, if we remember rightly—has wittily said that medicine had its first origins in priestcraft, witchcraft, and leechcraft; it is against a return to that state of affairs that our author protests. He traces briefly the history of ancient Greek medicine and of ancient Hindu medicine. The Hippocratic school appropriated ancient Hindu medicine; they found Ayurvedic doctrine good in general but imperfect in detail, and accordingly remodelled it, replacing wind by blood and subdividing bile. This alloy of East and West then passed through the Arabian school to the early English physicians of Chaucer's day. "Western medical practice of that day, based on these theories, was simple and direct. The body was depleted of its excess of humour by blood-letting, vomiting or purging, and the humour itself 'corrected' or made of proper constitution by an alterative. Astrology came in to determine the proper time to give the alterative."

There ensued a long period of history during which there was no advance. "To mediæval Europe these ancients had done their work so well as to leave to the modern nothing more to discover. Did Galen and Aristotle disagree concerning the number of teeth possessed by a horse, then the learned doctors would spend months in mental worry and dispute, trying to find some formula, or group of words, reconciling two conflicting statements, but never dreamt of looking into a horse's mouth, or asking a groom the way to tell its age."

Vesalius (1514–1564) was the first to modify the ancient creeds when in 1542 he published his celebrated work *Concerning the Structure of the Human Body*, and laid the foundations of modern anatomy. Then came Harvey's discovery of the circulation of the blood, which laid the foundation stone of modern physiology. It was now clear that the ancients had known but little or nothing; the road was once more open for enquiry. The nineteenth century opened and was to see the tremendous and revolutionary discoveries of Pasteur—who founded modern bacteriology, and of Lister—who founded modern surgery; also the discovery of anæsthetics.

From this origin modern scientific medicine began to permeate modern tropical medicine, and the days of the great pioneers of modern tropical medicine, of Vandyke Carter, Timothy Lewis, D. D. Cunningham, Sir Ronald Ross, Sir David Bruce, Sir William Leishman, ensued. To such an extent did tropical medicine advance that its rate of progress has outstripped that of modern non-tropical medicine.

That doctors bury their mistakes is a common cynical remark with a foundation of fact. Yet two generations ago post-mortem examinations showed that the doctors were nearly as often wrong in their diagnosis as right; today it is exceptional to find them wrong. Generation by generation modern medicine has accumulated a vast and progressive store of knowledge. Bright's disease must have existed for centuries before Dr. Bright of Guy's Hospital found that a particular group of symptoms during life was associated with a particular abnormal state of the kidney after death; yet the disease had never previously been identified as a separate entity. The most remarkable feature of modern scientific

---

medicine is that treatment is based on the *diagnosis* of the disease from which the patient is suffering; not upon his *symptoms*. It is the quack who treats his patients in accordance with the more obvious symptoms which they show; the medical practitioner knows that unless he can base his treatment upon ascertained and proved diagnosis he may do more harm than good. We have still to accept the Indian chowkidar's returns of death from "fevers"; but in our hospitals we strive to find malaria or kala-azar or other causative parasites in the patient's blood films.

This inheritance is of immense value, because with the increasing accuracy of observation and investigation, the value of the material becomes ever greater and greater. In fact it is to-day so voluminous that it requires abstracting and analysis in almost every branch of medicine, if its full value is to be made use of. Around the single subject of appendicitis, for instance, there is now a far more voluminous literature than Charka or Hippocrates ever wrote about the whole body of medicine. To-day the English farm labourer can demand from the modern hospital or from his panel practitioner an accuracy of diagnosis which the Queen-Empress could not have availed herself of thirty years ago. Should he fracture a limb a completely accurate diagnosis of the state of affairs can be obtained under the *x*-rays, and it can be ascertained under *x*-rays whether the fracture has been properly set or not. And the end is not yet; we are but at the beginning of still vaster expansions. Patients can sue medical practitioners for lack of skill, but on the other hand no claim can be made against a *vaid* or *hakim* for any greater degree of skill than that which existed two thousand years ago.

In chapter XIII the author turns to a most interesting analysis of the methods of the Indian indigenous systems. Essentially the *vaids* and *hakims* are compounders and prescribers of drugs. The death-rate from appendicitis in their hands is 10 per cent. as against 0.3 per cent. under modern surgical methods. "Wherever death is the possible issue of the case, *vaids* and *hakims* will leave behind more dead than the scientific man. That in itself justifies abolition of *vaid* and *hakim*, and their replacement by the better trained man, but the fact has to be faced that trained men are not yet available in sufficient numbers..... For the present, then, *vaids* and *hakims* are there and must remain there, but so long as they are there, India will keep what for Europe would be terrible death-rates." It cannot be too forcibly emphasised that modern scientific medicine is international, and not "Western"; it knows no barriers of country or continent; it explores and acquires knowledge wherever available. "Charka's physiology was a series of inspired puzzles; he wrote about wind and bile, but perhaps he meant ductless glands—or perhaps he did not. What he really meant is now and for ever in the future uncertain..... So long as they are given their correct value as speculations concerning what Charka might have said had he known more, no harm is done; but when they lead to a waste of public money the matter has a more serious aspect. The financing of Unani and Ayurvedic institutes by Governments in the hope of finding some soul of goodness in them is precisely on a par with the same Governments financing archery clubs to find out the possibilities of the bow and arrow in modern warfare..... It may well be asked if there are any possibilities at all in indigenous medicine. The answer is that *vaids* and *hakims* probably know of many useful drugs, but that their estimates of the usefulness of these drugs will require very careful examination on scientific lines before they can be accepted." Digitalis was introduced into modern medicine by an old Warwickshire country woman telling an eighteenth-century Birmingham physician that foxglove leaves were good for 'the dropsy.' He tried them, and found them good. But dropsy is a symptom of some fifty different diseases; digitalis was tried for all, and it fell into disrepute. Then the experimental pharmacologists set to work to examine its action on different organs of the body; they standardised it, and the modern cardiologists established its true value, and the cases in which it should or should not be prescribed. The same might be said of dozens of other drugs; ipecacuanha was formerly recognised as a drug of some value in dysentery; to-day emetine is reserved for proved cases of amœbic dysentery, when its use is invaluable.

Scientific medicine will always be proud to acknowledge the past; to accord to Hippocrates, Galen, Charka, and Susruta the niches in history that are due to them. Their want of knowledge was not to their discredit. What they knew was entirely to their credit, and it made them richer in that knowledge than any of their contemporaries or predecessors. "But they did not build palaces to endure for ever, but buildings that were marvellous for their age. We can admire and protect what is left of what they built, as relics, but not as habitations."

* * * * * * * *

We trust that we have given some resumé of Dr. Burridge's most fascinating little book. It is dispassionately yet forcibly written. It states the facts. A politician may be content with a "gesture"; a medical man strives for reality. There can be no two or more "systems" of medicine in the world of to-day; there can be but a universal and scientific system of modern medicine—with national or local medical councils and pharmacopœias probably, and with national and local interests—but all of them parts of an incorporated and world-wide whole.

A Modern Radiological Department.

WE have received by a recent mail a reprint from the *Electrical Review* of October 26th, 1926 of a most interesting account of the new Radiological Department of the Royal Infirmary at Edinburgh, which was opened by H. R. H. the Duke of York on October 9th, 1926. The Department is probably the last word to date in radiological and electro-therapeutic work, and abstracts from the account given by the *Electrical Review* may be of interest to our readers:—

The Exclusive Electro-Medical Equipment of the Edinburgh Royal.

THE new Radiological Department of the Royal Infirmary at Edinburgh, which was formally opened on October 9th by the Duke of York, is claimed to be the largest and most completely equipped institution of its kind in Europe; indeed, it is doubtful if its equal exists in any country. Moreover, it is also probably the only department of its kind which has been planned, built, and equipped from start to finish entirely for *x*-ray work and electro-medical treatment, which is the logical method of attaining the high degree of efficiency demanded in modern hospitals.

The new building is 160 ft. long, with an average width of 60 ft., and consists of a basement and two floors; the structure has a steel framework throughout, with reinforced concrete floors and roof, the latter having been designed flat to support another floor, if necessary. The main walls have Craigmillar stone and precast concrete stone dressings, and adequate protection against *x*-ray radiation is afforded by the interior lining of the walls, which consists of barium slabs coated with barium plaster, the ceilings and floors having been similarly treated also.

Each floor is devoted to a different purpose; the basement houses all the machinery, large storerooms, and a mechanics' workshop. On the ground floor are the various rooms of the radiological section, and on the first floor the electrical treatment and massage work are carried out.

The machine room contains a G.E.C. motor-generator of 42 kw. supplying 200-volt, 50-cycle alternating current for all purposes throughout the Department, a motor-generator of 1 kw. supplying 80-volt d.c. at constant potential at all loads for electrical treatment purposes, and a 3 kw. rotary convertor operating on the 230-volt direct-current main supply; this latter machine

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

is for use with an emergency outfit. All the switchgear for these machines is erected near to them, including an eight-way distributing panel, where the alternating current from the large motor-generator is split up and conveyed by separately-protected circuits to the various pieces of apparatus. A special cable from the town's network supplies 460-volt direct current for driving the large motor-generator; at its point of entry in the machine room it is split up by means of a large d.c. distributing panel so that 230-volt direct current is available for lighting and power purposes throughout the Department.

This main direct-current light and power board, together with four sub-main control boards on the ground floor, were supplied by the Edison Swan Electric Co., Ltd.

Three oil-immersed high-voltage transformers are also installed in the basement, or machine room, each being directly under an *x*-ray room on the ground floor; the high-voltage current is conducted through the ceilings into the rooms above by means of conductors passing through special porcelain insulators. Each transformer is capable of an output of 100 milli-amperes at 150.000 volts (peak value), being controlled entirely from a trolley-type switchtable installed in each appropriate radiographic room on the ground floor. By this means the noise and vibration of the moving parts are kept out of the *x*-ray rooms, and work can be carried on in absolute silence. Each transformer and mechanical rectifier is enclosed in expanded metal cagework, on the outside of which is an illuminated sign which lights up immediately the operator in the room above starts the apparatus.

One special feature of the power installation is the B.T.-H. Tirrill voltage regulator, which operates in conjunction with the 42-kw. motor-generator and enables the voltage between no load and full load on the *x*-ray transformers (when all are being used at once) to be kept practically constant, any voltage variation due to load, or fluctuating supply pressure, being corrected and restored to normal within a fraction of a second. It has so often been the experience of operators of *x*-ray equipment than an unavoidable fluctuation of supply current results in inconsistency of radiographic results, that the question of voltage variation has become a very important one. It can, however, be satisfactorily dealt with as explained above.

On the ground floor, the chief rooms are as follow:—Deep therapy treatment room, superficial therapy treatment room, three radiographic and fluoroscopic rooms, a lecture room, and another containing an emergency outfit. The patients are received at the office next to the entrance door, whence they go to the waiting halls at either end of the corridor; they then proceed as required to the dressing rooms before passing into the *x*-ray or treatment room itself.

The equipment in the deep therapy room is used chiefly for the treatment of malignant or cancerous growths, and is of a special type employing high-potential transformers, condensers, and rectifying valves of the hot cathode type. Two patients may be treated separately or at the same time with the one set of equipment, which is capable of a continuous current output at 250,000 volts of 10 milliamperes. The *x*-ray tubes are entirely surrounded by 5 millimetres of lead, except the small aperture through which the *x*-rays are emitted. In all the rooms in the Radiological Department the walls are lined with specially manufactured tongued and grooved barium blocks which afford protection against *x*-rays equal to that of over 4 mm. of lead. The switchgear is located outside the treatment rooms, so that the operator works in complete safety from *x*-radiation. The doors are covered with 3 millimetres of lead, and special lead-glass windows through which the patients may be observed during treatment also provide the same degree of protection.

A smaller installation of the same type serves another room wherein such superficial work as ringworm treatment is undertaken; the output of this smaller continuous-current plant is half that of the larger one, namely, 10 milliamperes at 125,000 volts. A system of bells communicating with an indicator in the control room enables each patient to attract the attention of the operator, if necessary. In passing, it is interesting to note that an oscillograph record of the current curve of the above type of equipment resulted in an almost straight line, which means that the voltage generated is as near as possible direct, and therefore, ideal for *x*-ray work.

Three separate rooms are used for radiographic and fluoroscopic purposes, each having its own high-potential transformer situated in the basement as mentioned previously. The first is the radiographic room wherein the majority of the out-patients are dealt with. It contains a protective cubicle for the operator, built of protective blocks such as have already been described, which houses the portable trolley switchtable, controlling the transformer in the basement. Special overhead corona-less high-voltage connections in the form of aluminium tubes fixed to the ceiling convey the current from the point where the insulators emerge from the floor to the two tube stands and *x*-ray couch which the room contains. It is not necessary to make any alteration in high-voltage connections when changing from one piece of apparatus to another; all the operator has to do being to pull a cord, which changes over the connections automatically. The box containing the *x*-ray tube underneath in the case of the couch has lead protection equal to 3 millimetres of lead, and the tubes in the adjustable stands for over-couch work are also fully protected.

The second radiographic room, is reserved for stomach cases, and is equipped with a new type of screening stand, comprising three separate units, an *x*-ray couch, and a tube stand similar to that described previously. A feature of this room is a special piece of apparatus whereby a series of radiographs of the stomach may be taken very rapidly, the whole procedure being practically automatic. Each picture can, however, be seen on the fluorescent screen before the exposure is made.

The third room is given over to the examination of chest cases, the equipment comprising a three-unit screening stand similar to that in the stomach room, an *x*-ray couch, a tube stand for over-couch work, and a special form of apparatus for investigating the movements of the heart radiographically. This last instrument embodies several improvements suggested by Doctor Robert Knox, who first constructed a machine of this type at the Cancer Hospital, London.

A complete *x*-ray unit is installed in the emergency room, which can be operated from its own rotary converter quite independently of the 42-kw. motor-generator, and enables any case to be dealt with when the machine room has closed down for the day. The outfit is capable of carrying out all types of radiography, and is particularly simple to operate, thus being very suitable for use by any member of the Infirmary staff who may not be very familiar with *x*-ray work.

On the wall in this room is fixed a dental *x*-ray outfit of unusual design: an adjustable arm carries at its extremity all the necessary parts, consisting of a high-potential transformer, oil-immersed and capable of an output at 45,000 volts (r.m.s.) of 10 milliamperes; a current stabiliser, and an *x*-ray tube protected with a covering of lead glass. These items are all contained in a metal tank measuring 9 by 7 by 7 inches, and there is absolutely no danger of either patient or operator receiving an electric shock of any sort, all dangerous parts being out of reach and immersed in oil, which feature is a great convenience for dental work wherein the tube is brought comparatively close to the patient.

A lecture room large enough to accommodate 40 students is equipped principally with a projection lantern, 24 illuminated viewing boxes for inspecting negatives, and two stereoscopes. Illuminated viewing boxes and a stereoscope also form part of the furniture in the radiologist's and his assistant's rooms, where

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

the films exposed during the day may be inspected and reported upon.

All the developing and photographic work is carried out in the Department itself, a dark room on the ground floor having been equipped with the latest appliances to enable the large number of negatives exposed each day to be quickly dealt with; it is so situated that exposed films may be passed into it from the various radiographic rooms through light- and *x*-ray proof apertures, and new films taken from the dark room as required.

The first floor is occupied by the Electrical Treatment Department.

One room is equipped with remedial exercise and gymnastic apparatus only. The natural lighting and ventilation of this room, in common with others throughout the Department, are particularly good, making the working conditions very pleasant. Ventilation is efficiently carried out by means of a system of air ducts and high-speed electric suction fans in the roof tower; extraction takes place at the ceiling level, fresh-air inlets being provided in all rooms on the ground level. The building is heated, as is the whole Infirmary, on the vacuum steam radiator system.

Adjoining the gymnasium are two large rooms for male and female electrical treatment. Each is equipped with wall-type treatment boards from which various types of interrupted and galvanic currents can be obtained; it is these boards which are supplied by the 80-volt motor-generator in the basement. A Schnee bath with unbreakable receptacles for the arms and legs is installed in each room, together with many other modern appliances, including diathermy and high-frequency apparatus. Plain massage couches are placed round the walls of each room on which the patients recline while undergoing treatment.

At the extreme end of the corridor is a laboratory where any experimental or research work may be conducted.

It is useful to have a small room where any type of treatment can be given in cases requiring special attention, and with this idea in mind one room was equipped with a treatment board on the wall, diathermy apparatus with condensation couch, etc., while a smaller room contains mercury-vapour arc lamps for use for both general and local ultra-violet ray treatment. General irradiation by carbon-arc lamps (artificial sunlight treatment) has been provided for by equipping two rooms, one for male and one for female patients, with powerful hanging arc lamps, and also a portable type of arc lamp which is convenient for the treatment of patients who are unable to sit up. The control boards for these lamps are fixed to the walls of the rooms, but an emergency switch outside in the corridor will switch off both lamps if necessary.

The building was designed by Mr. T. W. Turnbull, Master-of-Works, and erected under his supervision.

Messrs. Watson & Sons (Electro-Medical), Ltd., Sunic House, Kingsway, London, W.C. 2, were entrusted with the work of designing the Department in respect of the *x*-ray and electro-medical apparatus, and were responsible for the supply and installation of this equipment.

Dr. J. M. Woodburn Morison, M.D., is radiologist to the Infirmary. Modern ideas call for a very high standard of efficiency in *x*-ray work, and not only does this new Department, which has cost approximately £52,000, meet all reasonable requirements in this respect, but it also marks a very important step forward in the science of radiology.

Thrombosis of the Spermatic Veins following Amœbic Dysentery.

IN the editorial in our issue of October 1926, we drew attention to the recent work by American observers on the possibility of *Entamœba histolytica* invading the blood stream and causing infection of organs other than the liver and brain, and mentioned Warthin's case of apparent infection of the epididymis with this parasite. In this connection the following case, reported by Dr. J. W. Tomb in the *Transactions of the Royal Society of Tropical Medicine and Hygiene* for November 1926 (Vol. XX, No. 4, p. 288), is of considerable interest:

A.B., a European male, aged 33, five years resident in India, with a clear history of freedom from venereal disease, was attacked with amœbic dysentery in October 1917, which was successfully treated by rest in bed for twelve days on milk diet, together with hypodermic injections of emetine gr. 1 daily, followed by oral administration of a course of emetine-bismuth-iodide. About two weeks after quitting bed he became aware of a sickening pain, which seemed to him to lie in his right testicle. On examination, the testicle and epididymis were found to be moderately enlarged and tender; the cord was markedly swollen, and situated on it, close to the external abdominal ring, was a small, exquisitely painful, nodule evidently caused by thrombosis of one of the veins of the pampiniform plexus. On account of pain he was unable to walk, and suffered also from nausea and loss of appetite. He stated that three years previously he had suffered inconvenience for some time from a pain in the same locality, somewhat similar in character but much milder in degree, and unaccompanied by nausea or any noticeable swelling in the testicle. This condition he attributed at the time either to the effect of a badly-fitting suspensory bandage which he was then wearing—but which he subsequently discarded—or to injury of the parts by the saddle of his bicycle on which he rode daily to and from his work. The treatment prescribed consisted of rest in an easy chair, with local applications of liniment of belladonna, under which the acute symptoms subsided in about three weeks, the condition gradually and completely clearing up within six months.

After the lapse of one year, during which time no symptoms of dysentery had manifested themselves, he was again attacked with this disease, which was similarly treated with emetine hypodermically and emetine-bismuth-iodide by mouth. On this occasion also, about two weeks after the acute symptoms of dysentery had disappeared and he had resumed his ordinary duties, the right testicle and cord became swollen and painful—examination again revealing thrombosis of one of the spermatic veins with a tender nodule situated in the same locality as before. Rest in an easy chair with local applications of belladonna was again prescribed, but although the acute symptoms, in this instance also, subsided to a great extent after the lapse of about three weeks, considerable pain and swelling of the cord and testicle persisted. During the succeeding six months he suffered from several relapses of dysentery, which were treated with numerous hypodermic injections of emetine; the right testicle and cord throughout this period remained swollen and painful; while a varicose condition of the spermatic plexus of the right side began to make its appearance. At this juncture he was invalided to England on six months' leave. During this period no further symptoms of dysentery were experienced, though treatment was entirely suspended and ordinary diet resumed. The tender nodule in the cord also diminished in size, with corresponding relief from pain, but the testicle remained distinctly swollen, and marked varicosity of the spermatic veins supervened, so that he himself described his scrotum as feeling to the touch like "a bag of worms."

It should, perhaps, be mentioned that towards the end of his leave in Europe the patient married, and though the pain and swelling in the cord and testicle did not wholly disappear for over a year and a half (during which time he suffered from several mild relapses of dysentery, treated on each occasion by hypodermic injections of a few grains of emetine), the varicosity of the spermatic veins cleared up within six months of his marriage and return to India, and has not since that time recurred, the condition now appearing to be permanently cured.

Reviews.

GENIUS, SOME REVALUATIONS.—By A. C. Jacobson. Messrs. Greenberg, New York. Pp. 160. Price, $2.50.

We are quite sure that we approve of Dr. Jacobson's most interesting and exceptionally well written book, but we are far from sure that we approve of his main thesis, which is that genius is inseparable from degeneracy. "Ironically enough," he writes, "it is in the outcast, disinherited, vagabond, criminal, defective, insane and generally abnormal elements of humankind that genius germinates, never in the well-bred—eugenically speaking—right-wing of the race. Let the 'respectable' wince if galled by this challenging truth."

It is impossible to define genius. The old hackneyed definition of it as a capacity for taking infinite pains is certainly untrue; many geniuses are extraordinarily slipshod; thus Strauss wrote his compositions on any scraps of paper available—the backs of old envelopes, and the like; these he frequently lost, whilst they were occasionally illegible even to himself. The handwriting of most geniuses is illegible, though a bad handwriting is not in itself evidence of the possession of genius. Critics of the great military geniuses have defined genius as a capacity for making other people take infinite pains; yet even this definition is wrong; the stupider the general, the more his troops suffer. Genius is something which can only be recognised, and not defined. Yet Dr. Jacobson claims that genius is the expression of a creative secondary personality. The ordinary man is a mass of repressions and inhibitions—a "civilised" individual. When some toxin—alcohol, the toxin of tuberculosis or of syphilis—paralyses the higher and the inhibitory centres, then genius may awake. Not that it *will* awake—for the like toxin may produce a Prospero or a Caliban; but only under such conditions is genius born. Hitherto, our psychologists have studied the Calibans of the race; is it not time that they studied the Prosperos?

With his main thesis outlined, the author sets forth its full exposition by illustration and precedent, taking literary characters only—since to include others would make his work unweildy. Genius, he will have it, is frequently drenched in alcohol, sustained by alcohol, inspired by alcohol. "There has never been a time since Osiris, Bacchus, Ceres and Saturn disputed the honour of the invention of alcohol and its introduction among men, when it has not played a part in the intellectual activities and cultural progress of the world." Julius Cæsar was anything but a teetotaller, Cicero loved to dine with Lucullus, Pitt and Fox deliberately prepared their speeches under the excitation of excessive indulgence in porter and port wine. The veritable epidemic of alcoholism which occurred in the Elizabethan era in England was coincident with the great intellectual awakening of that age. And the outlook for New York is black indeed; she has no Mermaid Tavern, so she will never produce a Ben Johnson or a Will Shakespeare. Robert Herrick, one of the sweetest of British poets, has been termed the British Bachhus; *Don Juan* was written under the influence of gin. "Alcohol" writes Jack London "is the august companion through which one walks with the gods; the enemy of life and the teacher of wisdom beyond life's vision." But this problem is now of only academic interest in the States; "Highly respectable 'linnets singing on the wrists of kings' (and captains of industry) we shall have, but in the aisles of time no organ voices shall be heard again. The horns of our intellectual elfland blow faintly and no new planet swings into the ken of the watcher of the skies. Our Kultur has razed the cathedrals of the mind and only the squeak of the field mouse is heard over the ruins of our once mighty temples. Where once the wine-press of Horace and Anacreon stood, we shall manufacture synthetics..... Fairy forests are in process of conversion into subway shorings. Our poets, standardised by a board of censors, shall sing of the munition factory and the energies of gasoline."

Tuberculosis is an even more important creative factor than alcohol. The life of the tuberculous patient is shortened physically, but quickened psychically in a ratio inversely as the shortening. And here the list of tuberculous geniuses is an enormously long one. Schiller, Keats, R. L. Stevenson exemplify the states of depression of the consumptive: Molière, Nelson, Chopin its moods of buoyancy. "Men of common clay are but 'the pans and the barrows of the porters of the fire'; our tuberculous geniuses 'are children of the fire itself, made of it, and only the same divinity transmitted, and at two or three removes.'" There follow illustrative chapters which deal with the records at large, and the list is an impressive one; St. Francis of Assisi, Voltaire, Rousseau, Madame de Stael, Balzac, Kant, Goethe, Milton, Samuel Butler, Pope, Sterne, Jane Austen, Southey, Shelley, de Quincey, Ruskin, Francis Thompson, Synge, Washington Irving, Emerson—the list might be continued almost indefinitely. Sidney Lanier, the greatest American lyric poet since Poe, produced nothing of real value until in an advanced stage of pulmonary consumption, when his genius soared and he wrote his finest work.

The author's nationality being what it so obviously is, Dean Swift gets a chapter to himself. It is usually held that he was insane, but the theory that genius and insanity are the same breaks down at every point; if it were true we should seek for our finest creative geniuses in our mental hospitals. The genius is usually, if not always, of insane temperament, but his creative work reflects the man at his best, that is to say, sunset. Insanity is the Nemesis of the delicately balanced genius, never his good angel. Swift was a pronounced neurasthenic; and the stimulus to his finest work was "the woes of Ireland."

Still a third factor in the crucible of genius is the mixture in parentage of different racial elements, and geniuses are often hybrids. Woodrow Wilson puzzled the great American nation, but he would have puzzled no Scot. If you mix Hottentot and Hollander, the progeny will be queer, but it may throw up a genius, since a multiplicity of subconscious personalities will result. Lord Brougham in his memoirs states that he was saved from obscurity by the fact that his father, in place of marrying mere ordinary Saxon blood, went North for his Celtic, Scottish bride. "The genius tends to be the product of mixed ethnic and nervously peculiar stock—stock so peculiar that it exhibits an unusual amount of badness. The human family pays dearly for its geniuses. Just as nature in general is prodigal in wasting individuals for the development of a type, so do we here find much human wastage apparently for a similar purpose." Genius, in fact, is the lily on the dunghill; the race does benefit in the long run, but at great cost, the cost being in terms of degeneracy. And again the list of geniuses which rose from such an origin is a long one; the elder Dumas was half negro; Mark Twain had Dutch, English and Irish blood; Lafcadio Hearn, a son of Greece and of Ireland, could live in a negro quarter in the Southern United States, marry a Japanese wife, and write divinely well. Poe—one of the most dual personalities who ever lived—was of Irish, Scottish and English blood. Ibsen, Nietzche, Hilaire Belloc and Havelock Ellis are other examples. William Sharp ("Fiona Macleod") was of mixed Scandinavian and Celtic origin. "All of which may mean, not a practical joke of the gods, as Bernard Shaw sees it, but very good intentions on their part."

We have perhaps quoted sufficiently from Dr. Jacobson's fascinating book to show its main purport. It is a book to make the prohibitionist weep, and the eugenist swear. Vagabondage, sexual depravity, eccentricity are others of the characteristics of genius upon which the author dwells. Bernard Shaw "runs a purely imaginative laundry in which all the soiled linen of the world is cleverly washed."..... "Metchnikoff alternated between attempts to commit suicide and to find the means of prolonging life indefinitely."..... "Though the personal and literary sins of the creative artist be as

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

scarlet, yet must he be forgiven seventy times seven if a masterpiece be created by him. It is this doctrine of atonement which makes thoughtful persons fear censorship so profoundly and tolerate derelictions so patiently. .....The greatest need of the genius, after all, is to be let alone. When 'discovered' he should be accepted as a legitimate social unit, though 'different' and seemingly dangerous."

Dr. Jacobson's book is eminently readable. Yet is he right? Could not far longer lists of geniuses who came from healthy stock be made out? From a scientific point of view, where are the 'controls' to his experimental findings? And what of the general multitude of non-geniuses? Perhaps the cleverest satirist of the bourgeoisie of to-day is Arnold Bennett, and if we are to believe his books the run of ordinary individuals tends to be just as alcoholic, as tuberculous, and as immoral as the genius. The "James Soames"—es of the world are not among its geniuses, nor among its criminals; yet—if we are to believe Arnold Bennett—when the veil is lifted from their secret lives, the result would almost warrant placing them among the degenerates. Fascinating as Dr. Jacobson's book is, we doubt its value as a scientific work.

DR. A. MITRA, M.B.: A SKETCH OF HIS LIFE AND CAREER.—By Pandit Anand Koul. Srinagar: The Kashmir Mercantile Printing Press, 1926. Pp. 10.

EVERY young Bengali should read the little sketch of the life of Dr. A. Mitra written by Pandit Anand Koul and published by the Kashmir Mercantile Press, Srinagar.

Ashutosh Mitra was born in Calcutta in 1895, and from childhood he showed evidence of outstanding ability and personality. After taking the degree of M.B. of the Calcutta University, he went to England for two years of post-graduate study, taking the diplomas of L.R.C.P. and L.R.C.S. of Edinburgh. On his return to India, he leapt into success as a private practitioner. In 1885, he was selected by the late Maharaja Sir Pratap Singh as Chief Medical Officer of Kashmir and the rest of his life was devoted to the service of that State. In spite of the pressing claims of professional and administrative work he found time to make contributions to the literature of medicine, for instance a paper on nerve stretching in the treatment of leprosy, and a booklet on plague.

His success as a medical administrator resulted in ever increasing burdens being placed on his shoulders, and no less than nine departments were entrusted to him, namely, Jails, Municipality, Education, the Chemical Laboratory, Zoological Gardens, Sanitation, Meteorology, Museum, and Public Library. All of these departments were thoroughly reorganised and ably controlled by Dr. Mitra.

His personal courage was illustrated when he was called on to quell a riot in the jail after all the guards had fled before the mutineers. In this he received a wound on the head, but showed a resolute front to the rebels. Again in the terrible cholera epidemics of 1888 and 1892 he worked with almost superhuman energy. When plague broke out in 1902 he showed similar resolution and adopted drastic measures to stay the pestilence.

He was responsible for the introduction of a proper water-supply to Srinagar, and for the saving of thousands of lives by this and other measures of sanitation. His one great pleasure was work; play and social distractions made no appeal to him, his words were few and well chosen except when he was engaged in the missionary work of instructing the people in matters of health. His one great fault was that he had no mercy on his own body and his illness was largely due to his forgetfulness of his own physical welfare.

A great administrator, he had no use for party politics, and succeeded in maintaining the friendship and respect of all the opposing parties in the State. A born leader of men, he had the great quality of getting from his subordinates the best work of which they were capable.

By dint of merit he rose to the high position of Minister of the Kashmir State, controlling all the departments which came under his charge as Chief Medical Officer.

He busied himself with everything that was in the interest of the State, with other matters he did not concern himself, so that when the hand of death was laid on him the whole of Kashmir was plunged into deep mourning and paid him a remarkable tribute of respect.

His devoted widow, Mrs. M. Mitra, happily still lives; she also is imbued with the spirit of love for humanity, and in memory of her revered husband she has founded a Research Scholarship in Diabetes, the disease from which Dr. Mitra died. This scholarship is tenable by an Indian at the Calcutta School of Tropical Medicine, and the present holder—Dr. J. P. Bose—has made a number of valuable contributions to our knowledge of diabetes as it affects the people of India.

The life and work of Dr. Mitra should be prominently kept before the young men of Bengal as an example of what can be done if only duty to humanity is kept before them as their guiding star.

It would be well that this account of the life and work of Dr. Mitra should be a textbook in every school in India.

HANDBOOK OF MEDICAL ELECTRICITY AND RADIOLOGY.—By James R. Riddell, F.R.F.P.S. Edinburgh: E. & S. Livingstone, 1926. Pp. 239, with 110 illustrations. Price, Rs. 6-6 net. Obtainable from Messrs. Butterworth & Co. (India), Ltd., Calcutta.

WRITTEN for the student, this little book should prove a real boon. It is designed to present to him as briefly as possible a survey of those physical agents employed in the practice of medicine and usually found grouped together in the electrical department of a general hospital. The subjects dealt with include electricity, x-rays, radium, light, and carbon dioxide snow. The information given is thoroughly up to date. For instance paragraphs are devoted to such advanced methods as the examination of the lungs by means of lipiodol injections, and that of the gall-bladder by the tetraiodophenolphthalein method.

Of very moderate compass, this little book is packed with reliable information on the subjects dealt with, and should prove of value, not only to the student of medicine but also to the general practitioner, to both of whom it is highly commended.

THE OPHTHALMIC YEAR BOOK, VOL. XXII. 1926. —Edited by William H. Crisp. Chicago: Ophthalmic Publishing Company, 1926. Pp. 315, with 9 illustrations.

THIS excellent annual continues to supply a most valuable digest of the literature on this subject during the past year, and is invaluable in giving references and short abstracts, classified carefully and very easy to look up. This volume is well up to the standard of its predecessors.

OPHTHALMIC SURGERY AND SIGHT TESTING.—By M. A. Kamath, M.B. & C.M. Mangalore: Sadananda Co-operative Printing Works, Ltd. Pp. xi plus 150.

THIS small book is an extension of *Notes on Ophthalmology* by the same author, and is very much on the lines of the *Aids* series, while purporting to represent the teachings of the Madras Eye Hospital. It covers a great deal of ground, is very compressed and will probably be found useful by those who have been well grounded in the subject in hospital, reminding them briefly of work done, but the want of explanations or

Tests of Efficiency of the Dimol Duodenal Lavage.

Technique:

THE fæces were collected in two portions—Nos. 1 and 2—in sterile receptacles. Each portion was passed through filter paper under sterile precautions; cultures were then made from the filtrates on glucose agar plates, previously poured and incubated to prove sterility.

The cultures were incubated for 24 hours at 37·5°c.

Results:

Plate No. 1 A.—1 c.c. filtrate - - No growth.

Annual Reports.

ANNUAL PUBLIC HEALTH REPORT OF THE PROVINCE OF BIHAR AND ORISSA FOR THE YEAR 1925. BY MAJOR J. A. S. PHILLIPS, D.P.H., I.M.S., OFFICIATING DIRECTOR OF PUBLIC HEALTH, BIHAR AND ORISSA. PATNA, SUPERINTENDENT, GOVERNMENT PRESS. PRICE RS. 2-3-0.

LT.-COL. W. C. ROSS, I.M.S., was in charge of the department throughout the year, assisted by three Assistant Directors of Public Health and a temporary staff. The consolidation of the temporary establishment of the department into a permanent cadre directly under the Director of Public Health in order to increase its efficiency was effected after the close of the year.

General Conditions affecting Public Health.—The rainfall for the year was below normal in Bihar and Chota Nagpur, and above normal in Orissa. In July heavy rains caused floods in Orissa, and the rainfall was much above normal in October and December.

Vital Statistics.—The population of the province was returned by the census of 1921 as 34,002,189, exclusive of the Orissa States. This figure has been adopted in making the calculations in the report.

The birth-rate for the whole province was 35.6, as compared with 35.7 in 1924 and 37.0 in 1923. The general birth-rate for the towns was 32.5, against 32.9 in 1924 and 31.5 in 1923. The death-rate for the year was 23.7 for the province, against 29.2 in 1924 and 25.0 in 1923. The highest death-rates were those in Cuttack, Puri, and Balasore, and were due to widespread epidemics of small-pox and malaria of a severe type. The excess of births over deaths was therefore 11.9, as compared with 6.6 in the previous year. There was a slight decline in the birth-rate for the province and a marked decline in the death-rate, which is satisfactory.

The Director of Public Health has again pointed out that the low death-rates returned by the Dhanbad and Chakradharpur municipalities and the districts of Singhbhum and the Santal Parganas can only be explained by defective registration. In municipal towns 314 omissions in the registration of vital occurrences were detected by health officers and officers of the Vaccination Department from the 26,782 occurrences reported. In rural areas, however, verification work is negligible.

Epidemic Diseases. Cholera.—The total number of deaths from cholera was 17,336, which is 60,144 less than the figure recorded for 1924. This accounts for the marked decline in the provincial death-rate from cholera from 2.2 in the previous year to 0.5 in 1925. The highest death-rate (4.0) was recorded in the district of Purnea, the highest rate amongst towns being in Katihar (3.6), Forbesganj (3.4) and Buxar (2.6). There was an outbreak of cholera in the town of Bhagalpur. The measures adopted by the municipality for checking it were ineffective, and it was through the unsparing efforts of Lt.-Col. Cook, the Civil Surgeon, and a voluntary staff that the disease was brought under control. The assistant surgeons on the epidemic cadre were employed throughout the province in connection with outbreaks of plague, small-pox and malaria, at the Sonepur *mela* for propaganda work and at other times on investigation of disease. A special epidemic reserve of 100 vaccinators was also maintained for six months for cholera and other epidemic duty.

During the year vaccinators and kavirajes were trained in disinfection and in simple measures for the prevention of disease in order that their services might be immediately available in rural areas for the initiation of measures against epidemics. The distribution of Government's stocks of vaccine and of remedies for cholera, etc., continued to be made through the agency of Civil Surgeons. The adoption of kaolin as a household remedy for cholera was finally made during the year when its many advantages were fully recognized.

Small-pox.—The death-rate from small-pox was 0.4, against 0.2 in 1924, the increase being due to a serious epidemic in Orissa. The highest mortality was recorded in the district of Puri (3.8), Cuttack (1.7) and Balasore (0.8). The Director of Public Health has observed that secondary vaccination, which is the only means of prevention, should be made compulsory and free. He also considers that the Vaccination Act should be amended in order to raise the age for compulsory vaccination from six months to one year. Operations can now be performed throughout the province by trained vaccinators with pure vaccine.

Fevers.—The mortality from fevers fell from 19.3 in 1924 to 16.4 in 1925. The Director of Public Health has pointed out that in order to avoid the inconvenience of disinfection, vaccination, etc., certain infectious diseases are returned as fever at the beginning of an epidemic. This suppression of the real facts is most dangerous as it helps the spread of the disease. Government hope that the health officers of Government and of local bodies, during their tours in villages, will bring home to the people the evil consequences of such a course.

The sale of quinine treatments rose from 671.2 pounds of quinine sulphate in 1924 to 726.4 pounds in 1925. 1,090 lbs. of cinchona febrifuge was distributed free in Puri, Cuttack and Balasore where malaria was prevalent in an epidemic form.

Plague.—The mortality from plague showed a decline from 0.3 in the previous year to 0.2 in 1925, the decennial average being 0.7. It is satisfactory to note that the figures for 1925 are the lowest on record since 1905. For the last five years, however, plague has been levying a heavy toll in the town of Darbhanga. The visitation is ascribed to the breakdown of the conservancy and sanitary services of the municipality which thus has the remedy in its own hands. By proper sanitary precautions plague is preventable and the municipal commissioners must therefore be held responsible for its appearance at Darbhanga. For the province as a whole, however, the continued decline in the mortality from plague is gratifying.

Expenditure on Sanitation.—

(*i*) *Municipalities.*—The expenditure for sanitary purposes showed marked improvement under drainage, the figures being Rs. 2,04,703 in 1924–25 against Rs. 97,590 in the previous year. There was an increase in expenditure under conservancy also, the figures being Rs. 10,25,314 against Rs. 9,57,423 in 1924.

(*ii*) *District Boards.*—The most noticeable increase in the expenditure of district boards for sanitation was under water-supply, conservancy and epidemics, the figures being Rs. 2,05,890, Rs. 2,27,916 and Rs. 84,063 in 1924–25, against Rs. 1,65,102, Rs. 1,97,037 and Rs. 31,739 in the previous year. The proportion of sanitary expenditure to total receipts increased in municipalities and district boards as shown below:—

	1925.	1924.
Municipalities ..	33.4	31.5
District boards ..	3.1	2.6

The scheme of public health organization for district boards is at present working only in five districts. Government had previously prepared for the guidance of district boards a model scheme of a public health organization and had offered to meet half the cost of its adoption up to a limit of Rs. 10,000 in each district.

They have now prescribed the qualifications required of health officers whose appointment is a statutory obligation on district boards unless exempted therefrom. It is unsatisfactory to have to note that the adoption of a public health scheme is delayed in several districts by the board's anxiety to appoint unqualified or otherwise

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

incompetent health officers, or by their seeking sanction for alternative and usually impractical schemes devised by laymen without expert assistance. It is essential that the schemes in other districts should be introduced as early as possible, as it is on efficient district organisations that the general improvement of public health throughout the province depends. The Government Public Health organization can only be expected to supplement the efforts of local bodies in introducing sanitary measures and in combating epidemics after they have actually broken out.

Analysis of Food Samples.—A high percentage of adulteration continues as will be seen from the results of the examination of food samples given below:—

Ghee, 43 per cent. of samples analysed.
Atta, 92 per cent. of samples analysed.
Milk, 65 per cent. of samples analysed.

The adulteration of milk is especially noticeable as only 47 per cent. of samples were found impure last year. The Director of Public Health considers it very necessary that systematic action should be taken by local bodies under the Food Adulteration Act.

Work of the Medical Branch.—47 municipalities, 42 village unions and 33 high schools were inspected during the year under review. Lectures and addresses were delivered by touring officers of the Public Health Department and leaflets were freely distributed.

Seven municipal health officers continued to work as in last year, but their services terminated at the close of the year in four municipalities, as Government in view of their commitments to district board public health organisations were unwilling to continue to meet the salaries of municipal health officers. None of the municipalities so benefited has attempted to raise funds to maintain its own health officers, though most are conscious of the benefits thus derivable. The school medical officers visited 239 schools during the year, examined 12,222 pupils and delivered 1,313 lectures. About 7,000 leaflets, pamphlets, etc., were circulated through various agencies, including co-operative societies. The work serves a useful educative purpose.

During the year 1,200 items were examined in the sanitary laboratory, as compared with 988 in 1924. The Director of Public Health records a further advance in the bacteriophage research in connection with cholera which was continued in 1925.

The Director of Public Health and the Assistant Director of Public Health visited the Jharia mining settlements several times during the year and steady progress has been maintained in their work by the Jharia Mines Board of Health.

ADMINISTRATION REPORT OF THE MUNICIPAL COMMISSIONER FOR THE CITY OF BOMBAY FOR THE YEAR 1925–26. VOL. II. ANNUAL REPORT OF THE EXECUTIVE HEALTH OFFICER FOR 1925. BOMBAY. PRINTED AT THE *TIMES OF INDIA* PRESS. 1926.

Area and Population.—The area of the city is 23.54 square miles and the estimated population in the middle of the year 1925 was 1,259,414; on this estimated population the birth-rates and death-rates in this report have been calculated.

Births and Birth-rates.—Excluding 1,716 still-born children, the number of births registered during the year was 20,268 and was less by 1,570 than in 1924 and by 481 than the annual mean number of births registered in the ten years, 1915–1924.

The birth-rate calculated on the estimated population for 1925 was equivalent to 16.1 births per 1,000. Calculated on the census population for 1921, the birth-rate was 17.2.

As a check on the work of the staff engaged in the registration of births, the death certificate of every child dying under the age of 12 months is endorsed with the number of its birth certificate if the birth has been registered, and if not is marked "unregistered."

Deaths and Death-rates.—The total number of deaths registered from all causes during the year was 31,968, being 6,806 less than in 1924. It was 10,728 less than the average annual mortality of 1920–1924 and 10,844 less than the average annual mortality of the preceding ten years, 1915–1924.

Infantile Mortality.—Of the total deaths among infants, 1,553 or 22 per cent. took place in the first week of life and 967 or 13 per cent. in the age-period 1 to 4 weeks.

The mortality among infants who had not completed the first month of life was thus 2,520 or 35 per cent. of the total infant deaths. The number of deaths in the age-groups 1 to 6 months and 6 to 12 months was 2,199 and 2,573, being respectively 29 and 36 per cent. of the total infant mortality.

Summary of Work in connection with reduction of Infantile Mortality.—During the year the municipal nurses paid 45,452 visits to houses, chawls and huts (against 54,543 in 1924), enquired into 3,695 cases of ordinary sickness, and reported 288 cases of infectious diseases and 596 deaths in the female population of the city. They also attended on 1,455 confinements (against 1,842 in 1924) and verified the reports of the *birth karkuns* on 5,426 births. Of the women confined 1,868 were primiparæ.

Of the total number of 21,984 births (including 1,716 still-births) registered in the city during the year, 9,961 or 45 per cent. were verified by the municipal nurses as against 53 per cent. in 1924 and 63 per cent. in 1923.

Among the cases wherein enquiries were made, the proportion of births wholly unattended was 6 per cent. and that of confinements attended by unskilled women 44 as against 6 and 51 respectively in 1924.

Plague.—Plague did not assume epidemic proportions at any time during the year. The number of plague attacks was 192 against 450 in 1924. The disease caused 174 deaths in the year as against 409 in 1924 and 786, the average for 1915–1924. The mortality among reported cases was 90 per cent. as in the previous year. The number of deaths from plague was the lowest since 1896.

Plague Measures.—The usual preventive and precautionary measures such as, (*i*) inoculation, (*ii*) rat destruction, (*iii*) evacuation and (*iv*) disinfection were continued during the year: 5,850 persons were inoculated; 642,405 rats were destroyed, of these 315,185 were examined and 2,319 were found to be infected.

Small-pox.—Small-pox was prevalent in the city throughout the year and caused 570 deaths against 1,242 in 1924 and 594, the average for the preceding ten years (1915–1924). The number of attacks from small-pox registered during the year was 975 (including 23 imported cases) against 2,097 attacks in 1924.

Vaccination.—There are 19 vaccination stations in the city. The total number of primary vaccinations and of re-vaccinations performed during the year was 20,400 and 15,220 respectively, as against 20,135 and 26,508 in 1924.

The proportion of primary vaccination (13,544) in children under one year of age to the total number of births (20,268) registered during the year was 67 per cent.

Cholera.—There were 18 attacks and 12 deaths from cholera during the year as against 57 attacks and 34 deaths in 1924. Of the total number of cases 2 were imported.

Influenza.—The number of deaths registered as due to influenza during the year was 94. Diseases of the respiratory system to which deaths from influenza are frequently attributed were registered as the cause of death in 12,151 cases as against 118 and 14,410, respectively, in 1924. The number of deaths (94) from influenza in 1925 was 684 less than the average of the last five years (1920–1924).

Tuberculosis.—The number of deaths from tuberculosis was 1,404 and the dath-rate 1.11 per 1,000 of the population. Of these, 1,202 were due to pulmonary tuberculosis and 202 to other tuberculous diseases. There were 745 deaths among males and 659 among females. The disease caused a greater number of deaths

Schering

UROTROPIN-SCHERING

(Trade-Mark)

The original product prepared under the personal supervision of Dr. Nicolair. The most effective urinary antiseptic and internal disinfectant. **Supplied also in 40% Solution for intravenous injection.** For **infectious diseases, post-operative retention of urine and persistent vomiting during pregnancy.**

Original packing : tubes of 20×7½ grains tablets, glass of 1 oz. powder.

Solution (40%) 5×5 c.c. ampoules.

ARTHIGON

In this polyvalent vaccine the gonococci are suspended in solution of Urotropin, a method of preparation which ensures lasting stability in tropical climates.

Urotropin in combination with the killed gonococci produces a mutual increase of activity, the unspecific preparing the way for the specific stimulant. This vaccine is for use in gonorrhœal complications.

Easy absorption of inflammatory exudates with arrest of pain, occurs in **Epididymitis, Prostatitis, Gonorrhoeal Arthritis, etc.,** in progressive doses of 10, 30, 40, 50, 50, 100 millions per c.c.

Original packing : box of 6×1 c.c. ampoules, bottle of 6 c.c.

In obstinate cases we recommend a trial of our

ARTHIGON EXTRA STRONG

in 6 ampoules of progressive doses from 100 to 1,000 millions per c.c.

Original packing : box of 6×1 c.c. ampoules.

CYLOTROPIN

For injection, combining the antiseptic properties of Urotropin and Salicylic Acid with the diuretic effects of caffein. Excellent results have been obtained in **Cystitis, Pyelitis, Pyelonephritis and post-operative formation of concretions in the urogenital system.**

Original packing : For intravenous injection, boxes of 5×5 c.c.
For intramuscular injection, boxes of 5×5 c.c.

For full Clinical Samples with Literature apply to our Representative in India and Burma :

Mr. RICHARD SCHENK, 20-1, Lal Bazar Street, CALCUTTA, or from Messrs. T. M. THAKORE & Co., 24, Church Gate Street, BOMBAY.

among persons in the age-group of 20 to 40 years than in any other age period.

Anti-tuberculosis Measures.—There are two dispensaries for out-patients suffering from tuberculosis. Each dispensary is in charge of a medical officer and three nurses are employed for visiting the patients who attend, reporting on their house conditions and seeing that they follow in their homes the advice which they receive.

During the year under report the total number of tuberculous patients treated at the two dispensaries was 1,327; the number treated in 1924 was 1,302. The medical officers paid 2,661 domiciliary visits to see patients too ill to attend the dispensary.

During the year, 133 new patients were admitted to the sanatorium and 25 remained over from the previous year. Of these 38 were discharged improved or much improved; 72 were discharged at their own request; 28 died and 20 were under treatment at the end of the year.

Malaria.—Malaria was registered as the cause of 581 deaths, whilst 2,237 deaths were registered as due to ague and remittent fevers. Under the last two heads a number of deaths are no doubt included which were due not to malaria but to one or the other of the various diseases such as typhoid, tuberculosis and influenza in which fever may be a prominent symptom.

Anti-Malarial Measures.—Measures for gauging the incidence of malaria were continued during the year.

Spleen Rate.—The spleen rate for the whole city was 7.60 per cent. against 8.13 in 1924 and 7.80 in 1922.

Parasite Rate.—Out of 1,146 slides examined 37 showed parasites.

Quinine and Cinchona.—153 lbs. of quinine and cinchona febrifuge were supplied to patients and others free of charge through the 12 municipal dispensaries and other municipal agencies and at the municipal maternity and infectious diseases hospitals.

Wells.—Of the total 3,884 wells in the locality, 71 were filled in and 57 were covered during the year. 2,211 wells were examined for larvæ and in 318 of these larvæ were found.

Back Bay Reclamation.—Reclamation of the area in Colaba was in hand and the dredger was working up to the middle of May. It again commenced to work in November. The Medical Officer of the Development Department is looking after this area and treating the pools and puddles with crude oil. Larvæ of Anopheles mosquitoes were found to breed in these pools but they were not allowed to reach maturity as they were killed by the oil. A spleen census and an examination of the blood of the children in the labourers' camp in Colaba were carried out in 1925 by the special medical officer; 75 children were examined, two had enlarged spleens and two had parasites in their blood.

Venereal Diseases.—The number of deaths ascribed to venereal diseases during the year was 41 against 45 in 1924. Of the 41 deaths 39 were due to syphilis.

League for Combating Venereal Diseases.—Early in the year 1918, a League for Combating Venereal Diseases was established in Bombay under voluntary management, with the Head Office, Information Bureau and an Outdoor Dispensary at No. 66, Lamington Road. The management has been taken over by the Bombay Municipality from the 1st April, 1925. At the Information Bureau information and advice are given to the public and educational literature in English and the vernaculars is distributed. The dispensary is well equipped with all the necessaries for the three diagnosis and treatment of venereal diseases by modern methods. The staff of the dispensary consists of a medical officer-in-charge, a lady physician, a nurse and dispensary and laboratory assistants.

During the year ending 31st January, 1926, the number of patients registered in the dispensary was 2,284—1,744 males and 540 females. The average daily attendance of patients was as follows:—

Males.		Females.		
New.	Old.	New.	Old.	Total.
7	56	2	32	97

During the year under report 707 injections of neo-salvarsan were given and 341 Wassermann tests were made, besides a very large number of other injections and tests.

Sanitary State of the City.—The principal causes of the insanitary conditions which maintain the death-rate at a high level even in non-epidemic periods are the insufficiency of the water supply, the insufficiency of the sewers, the continuance of the basket privy system of conservancy, the density of houses and persons per acre and overcrowding of persons in rooms and tenements.

Water Supply.—The quantity of water available throughout the year has been well above the average, but the supply is intermittent and the pressure insufficient in many cases to fill the storage cisterns on the roofs of high buildings. Serious nuisance thus arises through the failure of the supply to the flushing tanks of water-closets.

Drainage.—Reference was made in some detail in the report for 1920 to the gravity of the insanitary conditions which result from the inadequacy of the present sewer system and the continuance of the old insanitary basket privies. The scheme for remodelling and enlarging the whole system is still under consideration and no progress has been made except in the construction of new sewers to be used when the location of the outfall has been decided upon.

Insanitary Dwellings.—The routine inspection of dwellings and premises presenting or likely to present sanitary defects has been systematised under a scheme whereby each one of the 50 medical assistants and 20 medical inspectors is required to devote not less than two afternoons a week to the inspection of houses in streets or areas definitely allotted for the purpose by the assistant health officers. The scheme aims at the inspection of not less than 10 houses per week by each member of the inspectorial staff or 35,000 houses in all in the year. Were inspection the single object in view, these numbers could be doubled or trebled. Since however the primary inspections are only the first step in securing the remedy of the sanitary defects discovered, their number is strictly limited by the number of secondary visits which the enforcement of the requirements of the department entails.

Six hundred and eighty-five insanitary dwellings were evacuated during the year, the great majority being insanitary kutcha huts.

REPORT OF THE BURMA PASTEUR INSTITUTE AND BACTERIOLOGICAL LABORATORY, RANGOON, FOR THE YEAR ENDING 31ST MARCH, 1926. BY LIEUT.-COL. J. TAYLOR, D.S.O., M.D., D.P.H., I.M.S., DIRECTOR. RANGOON, SUPDT., GOVT. PRINTING.

As far as one can gather from this report, Burma has not yet commenced the general issue of antirabic vaccine to out-stations. The result is a steady rise in the total number of patients treated at the Institute from 643 in 1924–25 to 1,092 in 1925–26, an increase of 40 per cent. in a year. In addition to this 692 persons were advised that treatment was unnecessary. This very high figure shows that the Burma Institute is careful to exclude most patients who are not at risk—a practice which it is desirable that other Institutes should follow.

Of 145 patients who voluntarily abandoned treatment no less than 125 were from Rangoon City, mostly labourers and menials. The practice of giving a bonus of Re. 1 to labourers and menials employed under the Rangoon Corporation who complete the course of treatment has not proved successful, and was abandoned towards the end of the year. Instead it has been decided that in the case of any employee of the Corporation or of any private firm coming for treatment, the employer should be asked to give a full day's pay for the half day's work of a person certified to be attending daily for treatment. This will mean that the individual under treatment will be at no financial loss.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Three deaths were reported among the 901 patients who underwent a full course of treatment, a death-rate of 0.33 per cent. Of these two only were failures of treatment, giving a failure rate of 0.22 per cent. Two of the deaths occurred among patients bitten on the head and Colonel Taylor, in a special table, emphasises the special danger of bites on the head. For the total figures for the years 1920–26 the death-rate amongst those bitten on the head was 6.3 per cent., in those bitten on bare skin on the trunk and extremities 0.51 per cent., and in those bitten through clothing 0.3 per cent. In other words, although bites on the head constitute only 3 per cent. of the patients treated, they are twelve times as dangerous as bites elsewhere on the body.

The usual statistical tables are appended to the report, and show certain features of antirabic work in Burma. Only 36 per cent. of the patients came from outside Rangoon: the monthly distribution in number of patients did not show any marked fluctuations; of 901 persons who received the full course of treatment, in only 18.8 per cent. was it proved that the biting animal was rabid by laboratory tests: no jackal bites occurred during the year: and reports were received on the health of 772 out of 835 persons treated. Of 138 brains sent for examination, 27 were in a condition unfit for examination—a testimony to the carelessness which prevails with regard to this important matter; every Director of a Pasteur Institute in India is familiar with the long succession of decomposed brains, decomposed dog's bodies, etc., which arrive for examination, and a good working rule is to have all such parcels opened *outside* the laboratory. The fixed virus was in its 535th passage on the 31st March, 1926.

Turning to the Bacteriological Section, a total of 4,551 routine examinations was called for during the year, and 210 autogenous vaccines were prepared. The Institute now stocks and supplies curative sera, and by storing in bulk it has been found possible to reduce the price of such sera. Cholera and influenza vaccines were issued on behalf of the Director of Public Health, and 387 samples of calf lymph from the Vaccine Depôt, Meiktila, bacteriologically examined. A pamphlet giving the methods of collecting and sending laboratory specimens was issued to all civil hospitals and private practitioners in the Province.

Research work was steadily continued during the year. An investigation into the keeping properties of carbolised antirabic vaccine shows that such vaccine will remain potent for two to three months, whether stored in the refrigerator or at room temperature. An enquiry is being conducted into the possible existence of schistosomiasis in Upper Burma, under a grant from the Indian Research Fund Association; whilst a second enquiry into beriberi in Burma is also being carried out under a similar grant. Special treatments have been instituted in the leper asylums of Burma under the supervision of the Institute, and 51,600 c.c. of hydnocarpus oil and creosote were issued during the year. The asylums were visited, and the results of treatment studied. Five lepers were treated at the Institute during the year and 341 injections given; the preparation was found to be non-irritant and was well borne; all five cases showed distinct improvement, and one apparent cure. Special research work was also carried on into methods of investigation of water samples.

In the covering note to the report Colonel A. Fenton, I.M.S., Inspector-General of Civil Hospitals, Burma, notes that as the result of the investigation into the keeping properties of the carbolised antirabic vaccine at atmospheric temperatures, it will now be possible to issue the vaccine, and that proposals will shortly be submitted for the establishment of out-centres for such treatment.

Lieut.-Col. J. Taylor, D.S.O., M.D., D.P.H., I.M.S., was in charge as Director during the year; Major C. de C. Martin, M.B., I.M.S., was Assistant Director; and Military Assistant Surgeons G. H. Blaker, I.M.D. and J. A. d'Costa, I.M.D., were Assistants to the Director during the year.

PASTEUR INSTITUTE OF SOUTHERN INDIA, COONOOR. ANNUAL REPORT FOR THE YEAR 1925–26. BY LT.-COL. T. H. GLOSTER, M.B., D.P.H., ACTING DIRECTOR. MADRAS, SUPDT., GOVT. PRINTING.

THE results of the policy of issuing antirabic vaccine to hospitals and dispensaries in the Madras Presidency, in place of making all patients go to Coonoor, is shewn in the following remarkable figures:—

Year.	Total number of Patients treated.	
1920–21	3,623	
1921–22	3,471	
1922–23	3,375	
1923–24	1,354	(first outside issue of vaccine)
1924–25	489	
1925–26	572	

whilst, out of the last total of 572 patients, no less than 335 came from Coimbatore district. Advice cases in the year numbered 155, and the virus was in its 973rd passage on February 28th, 1926.

On the other hand no less than 4,072 persons received treatment at local centres with vaccine issued from Coonoor. The total death-rates for (*a*) those treated at the Institute, and (*b*) those treated at local centres were respectively 1.04 per cent. and 0.61 per cent.; and the corresponding failure rates 0.69 per cent. and 0.39 per cent. On the face of it, this would appear to show that better results are obtained by the use of vaccine at local centres than at the Institute, but this conclusion does not of course follow. It is well known that the larger the number of patients treated, the lower becomes the mortality, since with increase in numbers more and more persons who are at little risk come to be included, whilst it is probable that the more serious cases would tend to go to the Institute rather than to local centres for treatment. Complete information also is only available from 69 per cent. of those who received a full course of treatment at local centres. Some local centres, such as those at Tanjore, Trivandrum and Mangalore reported on nearly 100 per cent. of the patients treated three months later; others—such as those at Calicut, Ernakulam, and the Victoria Hospital, Bangalore—furnished very defective returns.

Registration of deaths from hydrophobia has been in force in the Madras Presidency since 1913, and the collected returns are of considerable interest. Between the years 1913 and 1921 the total number of deaths per annum fluctuated between the figures of 89 and 140; but in the year 1922, when the first general outside issue of antirabic vaccine took place, the number suddenly leapt up to 220, and in 1924 no less than 364 deaths from hydrophobia were reported. This is probably due to the increased attention paid to hydrophobia as the result of the issue of vaccine to out-stations. The excess of deaths registered from hydrophobia in the Province over the small number of deaths recorded amongst those treated shows that only a proportion of persons bitten by rabid animals come under treatment, even with the present extended facilities. Of the total deaths registered in the Province since 1913, only 269 were among treated persons, whilst 3,195 occurred among untreated persons. It is probable, therefore, that very considerable expansion of antirabic work in this country will be called for in the future. Colonel Gloster estimates that during the years 1913–1924 some 60,000 persons were bitten by rabid animals in Madras Presidency, but that only about 10,000 of them—a proportion of 1 in 6—received antirabic treatment.

Part III of the report contains the usual statistical information with regard to the patients treated at the Institute. Europeans and Anglo-Indians treated during the year numbered 28 as against 544 Indians; 427 out of the 572 patients treated arrived within ten days of having been bitten; the monthly distribution of patients is fairly uniform, and there is little evidence of any seasonal variation in rabies in India; 4 out of the 7 deaths which occurred are classified as failures of treatment, i.e., deaths occurring more than 15 days after the end of treatment; 527 out of 572 patients came from

CAPROKOL

(HEXYL-RESORCINOL)

Issued also in olive oil solution in 4-oz. bottles.

The manufacture of Hexyl-resorcinol is protected by letters patent.

The **sole** licensees for the British Empire are The British Drug Houses Ltd., who **alone** are entitled to manufacture it within the Empire.

Hexyl-resorcinol B.D.H. is sold under the name of

CAPROKOL

and when prescribing this drug the name CAPROKOL should always be used.

The introduction of CAPROKOL has revolutionized the treatment of diseases of the urinary tract.

CAPROKOL is issued in capsule form in bottles containing 25, 50 and 100 capsules, respectively.

Caprokol is obtainable from our representatives resident in India,

HENRY S. CLARK,
8-10, Waterloo Street,
CALCUTTA,

BYRAM MISTRY,
119, Parsee Bazar Street,
Fort, BOMBAY, No. 1,

to whom application should be made for details as to prices and for descriptive literature.

Progress in the Treatment of Constipation

AGAROL is the *original* Mineral Oil—Agar-Agar Emulsion, and has these special advantages: Perfectly homogenized and stable; pleasant taste without artificial flavouring; freedom from sugar, alkalies and alcohol; no contraindications; no oil leakage; no griping or pain; no nausea or gastric disturbances; not habit forming.

IN the treatment of no other human ill has more definite progress been made than in that of constipation. Convincing proof of this is presented by

AGAROL

a remedy that in its composition not only exemplifies the latest study and research concerning the maintenance of normal bowel function, but by its practical use corrects functional intestinal derangements with a promptness and efficiency that leave no doubt of its superiority to ordinary laxatives and cathartics.

Prepared from the most carefully selected mineral oil and agar-agar, emulsified by special processes which ensure minute division of the oil globules and exceptional stability of the emulsion, and combined in proportions which extended clinical studies have shown to closely reproduce physiological conditions in the canal, it will be easy to understand why Agarol is so potent in its action, and so persistent and far-reaching in its effects.

Every day more and more physicians are turning to Agarol, and using it in preference to the old time evacuants, because they are finding, as Lawton did from his clinical experience with over 400 cases of constipation, that it "restores normal function through physiological channels" and marks a step forward in the rational treatment of intestinal stasis.

the Madras Presidency; jackal bites numbered only 8 cases out of the 572—a very low percentage and in marked contrast to the figures for such institutes as that at Shillong; 24 out of 193 brains received for examination for Negri bodies were in a condition unfit for examination; whilst it is noted that almost all the District Boards and Municipalities in the Presidency have continued to pay their annual contribution to the Institute, in addition to paying for the vaccine issued from the institute to out-stations. Sales of antirabic vaccine realised the sum of Rs. 41,459; the total income during the year was Rs. 69,374, and the total expenditure Rs. 49,898.

Lieut.-Col. J. W. Cornwall, C.I.E., M.D., I.M.S., held the post of Director up till January 28th, 1926, when he proceeded on leave prior to retirement, and was succeeded by Lieut.-Col. T. H. Gloster, I.M.S.

Correspondence.

THE COUNTRY *DAI* AND HER MINISTRATIONS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—I shall be much obliged if you will kindly allow me space in which to publish notes on the following two cases.

Case 1.—On the 28th Nov. 1926. I was called in to attend a labour case in the *mofussil*, about twelve miles from this town. On enquiry, I was told that the case was one of hand presentation and that labour had already lasted for two days. The man who called me wished me to bring a midwife with me, but I preferred to take the sub-assistant surgeon to help me.

When we arrived at the patient's house, the relatives did not wish us to attend the case, but after some two hours' discussion we were permitted to do so. The patient was lying in a small hut, with very little light, and dusk was drawing on. She was a multipara, the mother of six or seven previous children, and some 40 years of age. She appeared to be in sound health, but all labour pains had ceased since the previous night; the pulse was 91 per minute, and the temperature elevated. The bladder was distended and a catheter was passed and relieved this condition.

The labia were swollen, and on examination a piece of bone was found to be protruding from the vagina. On examination I found the case to be one of left handed presentation with the head on the right side. The hand of the fœtus had been torn off at the wrist. Foul smelling gas was escaping from the vagina.

Under chloroform anæsthesia I succeeded in carrying out internal version and in delivering the fœtus and placenta. The patient—to my surprise—made an uneventful recovery. The child, of course, was dead.

The special point about this case is that the untrained country *dai* who had attended the patient before I saw her had used sufficient violence to tear off the presenting hand, which she had concealed from everyone present. The amount of violence necessary to tear off a fœtal hand can easily be imagined.

Case 2.—On the 20th December 1926 I was called in to attend a labour case in a neighbour's house, and was told that the case was one of breech presentation. On reaching the house I found the *dai* still in attendance and pulling hard at the presenting parts. She informed me that she was doing her share of effort, but that the patient would not bear down sufficiently hard, as she had been directed to. On examination I found the fœtus with both elbows well jammed into the brim of the pelvis. I succeeded in bringing down the arms, but the chin rotated forwards and became fixed. The aftercoming head gave considerable difficulty, and after some time a well-developed but dead fœtus was delivered.

A live child could have been delivered in this case had it not been for the ministrations of the so-called "expert" *dai*.

How long is India going to put up with such barbaric midwifery?—Yours, etc.,

TARAK NATH CHAKRAVARTY, L.M.S.

NILPHAMARI,
11th February, 1927.

THE INDIAN SCIENCE CONGRESS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—It was a matter of satisfaction to see the great interest shown by the Medical and Veterinary Section of the Indian Science Congress in the deliberations at Lahore last January, and more so because the number of papers sent exceeded all previous records. One may anticipate a similar increase in the next year's Congress.

Considering the time at disposal at any single session, to strike an average one gets 12 papers per day of 3 hours work, a time which is very unreasonable both to the author and to the large audience who attend, especially the younger of my age with a desire to pick up new ideas and newer work on older known things.

May I suggest that papers of prime importance involving original work or original ideas should be given a much longer time for the author to detail as much as he likes?

At Lahore it was observed that a great deal of the time was spent in a sort of popular talk about prevention, etc., thus leaving aside some very original papers, e.g., those by the President and Lieut.-Col. H. W. Acton, nearly unread or taken as read.

If it would not be presumptuous on my part, as I very keenly follow the medical and veterinary research work from year to year, I would make the following suggestions:—

The papers be grouped in distinct classes, as follows:

(*a*) Papers relating to original work or original ideas, e.g., the theory of acquired angiomata by Colonel Acton, "Vaccinia Virus" by Dr. Pandit, etc.

(*b*) Papers relating personal observations of scientific technique; e.g., the pharmacological work by Major Chopra, the production of a tumour by inoculation of *B. lepræ* by Dr. Muir, and the physiology of the coronary circulation by Prof. Cruickshank.

(*c*) Papers relating to the invention of instruments or apparatus of a purely physical or chemical nature, or papers relating to animal or plant life useful to medical science, e.g. "Fish in the control of mosquitoes" by Hora; an apparatus for recording the temperature of insects by Colonel Acton; a cold incubator, etc.

(*d*) Papers embodying personal observations of a controversial nature, new methods of treatment (the idea alone being narrated without details of clinical work), e.g., "Sanocrysin in the treatment of Tuberculosis" by Möller.

(*e*) A number of papers which the authors wish to be brought to the notice of the Congress to be allowed only if printed copies are supplied and to be taken as read.

Under the last heading will come all papers on tuberculosis, child welfare, statistics, etc.

In case there is a large number of members desirous of discussing one single subject, printed summaries being circulated one day previous, all the interested members can have a sectional meeting for discussion, specially on the day on which the presidential address is delivered, as this address is generally of general interest of wider scope.

If the papers are taken up in this order, the best material will get the greatest scope and will receive the honour hard and laborious work deserves. It was a pity that some of the best papers were dismissed in a very short time and an amount of time wasted over popular discussions which knew no end.

This is in no way meant as a criticism on the management of the Section, but is a humble suggestion from an eager listener, interested in scientific medicine.

An important idea was expressed by the President in his address about the establishment of a Central Research Institute in Pharmacology and is very inviting. With a view to setting out the strength of the Medical and Veterinary Research Section will it help to issue

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

a questionnaire to the members asking them to give their names, qualifications, places of work, the persons under whom they were trained, the personnel under their training, the scope of their work, the subjects in which they are interested, and the source of funds for the work? This may be of use to some extent to see how far we are in need of such an organization as a large Central Research Institute for the country and what chance it has of being efficiently manned.—Yours, etc.,

P. V. GHARPURÉ.

GRANT MEDICAL COLLEGE, BOMBAY,
18*th January*, 1927.

NEURASTHENIA IN THE TROPICS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—May I have your permission to endorse the hope of Major R. Knowles, I.M.S., that the very interesting paper on "Neurasthenia" read recently by Lieut.-Col. H. W. Acton, I.M.S., before the Medical Section of the Bengal Asiatic Society, will attain the intensive study and appreciation which it so richly deserves? As might only be expected of him, Colonel Acton has given his colleagues the world over a very illuminating study of neurasthenia, and that too in the sense of the disease which most neurologists nowadays take to be the correct one. Hence from the strictly neurological standpoint there is very little in the views of Colonel Acton as to the etiology and treatment of neurasthenia to which anyone could take serious objection, except and in so far as he makes the sexual factor a secondary and not, as I hold it to be, a primary one. In the discussion that followed Colonel Acton's paper, Colonel Green-Armytage shewed a strong appreciation of the importance of the sexual factor in the etiology of neurasthenia, but in that he cited "coitus interruptus" as a prominent feature in the causation of this neurosis, one is at liberty to presume that this eminent gynæcologist confuses neurasthenia with anxiety neurosis. On the other hand, Colonel Green-Armytage is, I think, perfectly correct in citing excessive masturbation, in women as well as in men, as a potent influence in the production of neurasthenia. From my own experience, as well as from much study of neurological literature, I have reached an almost unshakeable belief in the correctness of the Freudian theory that real neurasthenia arises solely through a conjunction of an excess of efferent stimulation with a serious defect in afferent stimulation. Further, all those subjective feelings of physical ill-being, to which Colonel Acton calls attention, especially those associated with the alimentary and excretory functions, arise secondarily from a repercussion of thwarted *libido* upon secondary erogenetic zones. In these circumstances, it should be obvious that the only prescription that can be of any real value to the patient, is a return to, or, as the case may be, an institution of, a normal *vita sexualis*.—Yours, etc.,

OWEN BERKELEY HILL, M.D. (Oxon.),
Lieut.-Col., I.M.S.

RANCHI EUROPEAN MENTAL HOSPITAL,
25*th January*, 1927.

QUININE-UREA INJECTIONS IN MALARIA.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—In continuation of my previous letters on this subject, my attention has been arrested by the following passage in Messrs. Parke Davis and Co.'s *Index of Materia Medica and Therapeutics*, 1927, at the foot of p. 107. "The combination of quinine and urea is said to be superior to any single quinine salt in malaria (*Brit. Med. Jour.*, Epitome, 1908. Vol. II, p. 91)."

Also a reference to Dr. Leo von Gordon's article in the *Schweizerische Medizinsche Wochenschrift* suggests that the double salt of calcium chloride and urea is useful in fevers; and—recollecting that the combination of antimony with urea has up to the present proved to be the best remedy in the treatment of kala-azar—it seems possible to me that the combination of quinine with urea may be found to be of definite value for injection in cases of malaria, as I previously suggested.—Yours, etc.,

J. E. LEONARD CHINAL, M.D.,
D.T.M. (Bengal).

MONGHYR,
13*th January*, 1927.

A CASE OF NASAL MYIASIS.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—The following notes on a case of nasal myiasis may be of interest to your readers.

Three years ago a male adult patient from a village near Baroda consulted me for intense pain in the head and a serous discharge from his nose. The pain was of an unbearable character, and the patient continuously tossed his head from side to side both day and night. On examining the nose an inflammatory condition of the mucosa was found, and whilst douching the nose the next day a maggot was detected in the discharge.

I immediately put the patient on to an alkaline nasal douche and turpentine drops. Maggots came out from both nares in bunches of 15 to 20 at a time, and in the course of three or four days he was much relieved. He was then advised to go home, but to continue the nasal douching and treatment.

Two weeks ago he returned to my dispensary with the same symptoms. I had no hesitation in making the diagnosis. He was again treated in the same manner, and has again made a (possibly temporary) recovery. It is difficult to say whether the second infection is a relapse of the former one, or a newly acquired one. Normally the patient is able to sneeze and to detect smells and odours. He is neither syphilitic, nor leprous.—Yours, etc.,

VENILAL N. MODI, M.B., B.S.

RAOPURA, BARODA STATE,
19*th January*, 1927.

(*Note*.—We believe such cases to be not uncommon, but would welcome information on the best lines of treatment. During the war in Mesopotamia in 1914–15, after the battles of Shaiba and Nasiriyeh, many of the Turkish and Arab wounded lay out in some instances for days before they were collected, and very many of them showed heavy myiasis infection of their wounds. In some instances, where wounds of the limbs were swarming with maggots, amputation was found necessary.—EDITOR, *I.M.G.*)

VACCINATION AND FEMALE EDUCATION.

To the Editor, THE INDIAN MEDICAL GAZETTE.

SIR,—Government has posted vaccinators throughout India in order that small-pox may be eradicated from this country. Why, then, do epidemics of small-pox occur? This cold weather there has been a severe outbreak in this side of the Punjab, and in many villages the scenes witnessed have been almost unbearable, whole villages being infected, and the mortality rates high.

The reason is that the women of India are uneducated. On the arrival of a vaccinator in a village some mothers carry their children away immediately to another village in order that they may escape vaccination. Others, who cannot so escape, have their infants vaccinated and then immediately remove the lymph by sucking or by washing it off. These ignorant women do not believe in vaccination. The only method to save India from epidemic outbreaks of small-pox is to improve the state of affairs with regard to female education.

This *tahsil* is 64 miles long by 48 miles broad. The total expenditure in it on female education is Rs. 51 *per mensem*. With so trivial an expenditure on female education the mortality from small-pox and other epidemic diseases can never be diminished.—Yours, etc.,

RUDRA DUTT,
Assistant Surgeon.

MAILSI,

A

Vitamin-containing food —and very much more

Whilst the presence of vitamins in food is rightly recognised as essential, their presence is a minimum and not a maximum requirement. Whilst Virol contains all the vitamins, it does not, like so many foods, found its claim to medical attention on its vitamin content alone.

In Virol the relative proportions of Protein, Fat, Carbohydrate and Mineral Salts are carefully adjusted. For it is recognised that the absence or deficiency of one element leads to the inefficient absorption of the other food elements present in the diet. Thus

Virol is a food complete in itself and correctly balanced

A Food, again, must be judged by the amount and nature of the products of its digestion that ultimately reach the blood. In Virol the fat is presented in the form of a highly digestible emulsion, and the proportion of protein is adjusted so as to avoid derangement of nitrogenous metabolism.

The proof that Virol conforms to all the essential canons of the science of nutrition is seen by the fact that

VIROL

is used in over 3,000 Hospitals and Welfare Centres

INFANT FEEDING ON SCIENTIFIC LINES

WHEN artificial feeding has to be adopted, either entirely or in part, the "Allenburys" Progressive System of Infant Feeding fully meets the case. The "Allenburys" Series of Foods is arranged on a true physiological basis; it provides a progressive dietary suited to the development of the infant, supplying at the appropriate times the stimuli that call forth, in a natural way, the secretion of the digestive enzymes.

The "ALLENBURYS" MILK FOOD No. 1 is adapted to the first three months of life. It is a scientifically balanced nutrient which when prepared for use, is similar to human milk in composition, physical properties and ready digestibility. *It contains no starch.*

The "ALLENBURYS" MILK FOOD No. 2 is used from the beginning of the fourth month to the end of the sixth month. It is similar to the No. 1 Food except that it contains a proportion of the soluble phosphates, albuminoids and sugars obtained by the digestive action of malt on whole wheat. *It contains no starch.*

The "ALLENBURYS" MALTED FOOD No. 3 is for use from the beginning of the seventh month. It consists of a carefully selected wheaten flour of a high albuminoid content, so treated as to render it easy of digestion, together with a proportion of the diastasic and nutritive constituents of malt. When prepared for use it contains no unaltered starch.

The "ALLENBURYS" MALTED RUSKS are made from special flours rich in protein and provide the infant's first solid food. As early as the fifth month these rusks may be used, a little at a time, to aid the cutting of the teeth. From about the tenth month they may be given as a staple article of diet in conjunction with the Malted Food No. 3.

The "Allenburys" Foods are designed particularly for Infant Feeding and are manufactured by special processes which make them peculiarly suited for this purpose. They are constant in composition and free from any pathogenic organisms.

A copy of our new publication "The 'Allenburys' Foods in Infant Feeding" will be sent post free on request.

OBITUARY.

WE regret to record the death from heart failure on January 19th, 1927, of Sir Kailas Chandra Bose, one of the most distinguished medical men in India, and one of her greatest benefactors.

Kailas Chandra Bose was the second son of Babu Madhusudan Bose, a member of a famous Bose family of Simla, resident in Calcutta, and was born on the 26th December 1850. His father and the members of his family were the pioneers of steamship communication on the River Hughli, were well known in commercial circles, but also distinguished for their patronage of science and literature. After passing through school with considerable distinction, K. C. Bose entered the Calcutta Medical College, from which he graduated in the Calcutta University in 1874. At first he entered government service as Resident Medical Officer, Campbell Hospital, Calcutta, but was persuaded by a brother to leave government service and to set up as a private practitioner. Within two years he had secured in Calcutta a brilliant reputation, and had established a lucrative practice, especially among the Marwari community. It was not long before he was recognised as the leading Indian medical practitioner in Bengal.

He was President of the Calcutta Medical Society, Vice-President of the first Indian Medical Congress, a Commissioner of the Calcutta municipality in 1899, and was created a Rai Bahadur in 1895. In recognition of his valuable services to Bengal he was further created a Companion of the Order of the Indian Empire (C.I.E.) in 1900, and a Fellow of the Calcutta University from 1904 onwards. His public work was recognised by the award of the Kaiser-i-Hind gold medal in 1910, and in 1916 he was knighted, being the first Indian doctor to receive this honour. Amongst other honours which fell to him were the

The Late SIR KAILAS CHANDRA BOSE, *Kt.*, C.I.E., O.B.E.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Order of the British Empire in 1918, membership of the Governing Body of the State Medical Faculty of Bengal, and the presidentship of the Antimalarial Co-operative Society. He was also an honorary presidency magistrate.

From first to last Sir Kailas' career was characterised by two special features, his great professional ability, and his intense philanthropic interest in the hospitals and charitable institutions of Calcutta city. The first brought him wealth, which he expended upon the second. He was a man of very great personal charm and force of character, an Indian of the old school who believed strongly in the British connection, and an idealist. In controversy he did not hesitate to tell the truth, however unpleasant, and his opinion was listened to and deferred to in a way that would not have been possible to anyone less an idealist and a seeker after truth. His convictions and his personal courage led him to brush aside the conventions of diplomacy and the unrealities of politics, in which he never mingled.

Among his innumerable philanthropic activities his collection of funds for the establishment of the Bengal Veterinary College and Hospital was a notable event. In addition he collected a sum of Rs. 36,000 for the erection of kennels and the provision of veterinary ambulances. The cottages for paying patients at the Calcutta Medical College Hospitals were constructed through his exertions, in which connection he raised a sum of nearly 1½ lakhs of rupees. A sum of Rs. 20,000 was contributed by one of his friends in recognition of his work to the Prince of Wales Hospital, Calcutta, for equipment for surgical work. He raised Rs. 12,000 for the endowment fund of the Lady Dufferin Hospital. Finally his most notable effort was his long and close personal association with Sir Leonard Rogers in arousing interest in the scheme for the Calcutta School of Tropical Medicine, and in collecting funds for its endowment. In effect, Sir Kailas Chandra Bose and Sir Leonard Rogers, after raising very considerable contributions for the scheme from the Indian community in Calcutta were in a position to go to the European commercial community, and point out the necessity for their also supporting the scheme. A sum of two and a half lakhs was raised by Sir Kailas for this project, and the School owes its inception not less to the efforts of Sir Kailas than to those of Sir Leonard Rogers. He gave personally a further sum of Rs. 5,000, and the Kailas Chandra Bose ward for Indian males in the Carmichael Hospital for Tropical Diseases was named after him.

Further philanthropic efforts on his part resulted in his raising a sum of Rs. 40,000 for a pilgrim rest house at Puri, and a further sum of Rs. 13,000 for a separate female ward in the Puri Pilgrim Hospital. Other endowments which he raised were for the supply of a pure drinking water-supply for pilgrims at Puri, and a sum of nearly half a lakh of rupees for the improvement of the leper colony at Puri. He also collected a sum of Rs. 65,000 and placed it at the disposal of the Government of Bengal for the construction of a zenana bathing ghat close to Howrah bridge; and further sums totalling Rs. 75,000 for the pilgrim rest house at Kalighat. Further exertions on his part resulted in raising a sum of Rs. 65,000 for opening the park and recreation grounds in Kidderpore, and a sum of Rs. 50,000 for a maternity home for Indian women, recently opened by H. E. the Governor of Bengal. There is hardly a hospital for man or beast or a philanthropic institution for the benefit of suffering humanity in Calcutta that does not owe him a debt of the deepest gratitude.

His activities were not confined however to philanthropic work. In the days when Calcutta was faced with a plague scare, his great influence was thrown into the scale to steady and rally public opinion in favour of the measures proposed. He opened no less than eight private plague hospitals for the treatment of patients of respectable class who refused to go into the ordinary segregation hospitals. During the Great War he carried out an intensive campaign on behalf of the Government of India War Loans, succeeding in securing the investment of over two crores of rupees. Finally, he has left in the literature a long series of some thirty or more medical and scientific papers, dealing with such diverse subjects as epidemic dropsy, cholera in Bengal, small-pox, diabetes among Bengalis, the use of drugs of addiction in India, water supplies, tanks, and town-planning.

Sir Kailas was a man whom it was an honour and a privilege to have known. Dignified, courteous, stately in presence, he was an ideal host. In speech he was never hurried, spoke slowly, and never gave anything but his matured judgment. At the meetings of the Governing Body of the Endowment Fund of the Calcutta School of Tropical Medicine his advice and his help from the Indian point of view were invaluable; he was ripe in years, experience, and wisdom. Further, there was no Indian in India with a clearer vision of both past and future, and none whose considered opinion carried more weight. Whether the matter under discussion affected the Calcutta University, the School of Tropical Medicine, or the Medical College or other charitable institution, his advice and his opinion were always eagerly sought for, though not always immediately given. Further, his extensive practice and extensive

Milk Diet

In all diseases in which there is pyrexia—and notably in typhoid fever—physicians are obliged to resort to milk diet.

Ordinary milk swarms with bacteria, and this adds to existing irritation of the mucous membranes.

Glaxo is milk made clean, pure and germ-free by the noted Glaxo process. Glaxo is more palatable and more easily assimilated than the best cow's milk.

TRUE PARATHYROID

Oral parathyroid therapy increases the blood calcium index with coincident healing of ulceration of years' standing. But it is essential to have TRUE parathyroid, free from extraneous tissue and especially free from thyroid. Like all HARROWER preparations

PARA-SPLEEN Co. (Harrower)

(formerly Parathyroid Co.)

is the product of specialists and that is why it has demonstrated its usefulness in so large a number of cases of SPRUE; varicose ulcers; gastric and duodenal ulcers; ulcerative colitis; tuberculosis, etc.

PARA-SPLEEN Co. (Harrower) is put up in tablets for oral adminstration; or in solution in one c.c. ampoules, for intramuscular injection.

acquaintance among the wealthy and commercial Indian communities of Calcutta enabled him to sound real Indian opinion with regard to different philanthropic projects in a way that would have been impossible to almost any other citizen of Calcutta.

In Sir Kailas Chandra Bose, Calcutta loses one of her greatest and most representative of citizens, and Bengal one of her foremost pioneers. His loss will be keenly felt by both the European and Indian communities of Calcutta, whilst the memory of his unstinted generosity and of his splendid philanthropic efforts will remain as a tradition for the future.

Service Notes.

APPOINTMENTS AND TRANSFERS.

Major-General F. H. G. Hutchinson, C.I.E., M.B., I.M.S., to be Honorary Surgeon to the King, Indian Military Forces, *vice* Major-General Sir R. C. MacWatt, K.C.I.E., M.B., F.R.C.S., I.M.S. (retired), 1st October, 1926.

The King has been graciously pleased to give orders for the following appointment to the Most Honourable Order of the Bath:—

To be Ordinary Member of the Military Division of the Third Class, or Companion of the said Most Honourable Order.

Colonel C. Hudson, C.I.E., D.S.O., F.R.C.S.E., I.M.S., Assistant Director, Medical Services, Aden Brigade, Aden.

Lieutenant-Colonel D. Heron, C.I.E., I.M.S., an Agency Surgeon, on return from leave, is posted as Residency Surgeon, Mewar, with effect from the 15th January, 1927.

The services of Lieutenant-Colonel J. Morison, M.B., I.M.S., Assistant Director, Haffkine Institute, Bombay, are placed temporarily at the disposal of the Government of Burma, with effect from the 30th November, 1926, for appointment as officiating Director of the Pasteur Institute, Rangoon.

On return from leave Lieutenant-Colonel M. Mackelvie, C.I.E., M.B., F.R.C.S.E., I.M.S., is appointed to be Civil Surgeon, Dacca, with effect from the forenoon of the 31st January, 1927.

Lieutenant-Colonel W. L. Harnett is appointed to officiate until further orders as Professor of Clinical and Operative Surgery, Medical College, Calcutta, *vice* Lieutenant-Colonel H. B. Steen, granted leave.

Lieutenant-Colonel C. A. Godson, M.C., I.M.S., is appointed Civil Surgeon of Hooghly, with effect from the afternoon of the 12th January, 1927.

He is also appointed to act as Civil Surgeon of Serampore in addition, with effect from the same date, until further orders.

The following officers of the Indian Medical Service are appointed substantively to be Agency Surgeons under the Government of India in the Foreign and Political Department, with effect from the dates shewn against their names:—

Major W. J. Simpson—13th August, 1924.
Major F. Stevenson—5th October, 1924.
Major C. H. Smith, O.B.E.—8th April, 1925.
Major L. H. L. Mackenzie—17th July, 1925.

The services of Major H. S. Anand, I.M.S., are placed temporarily at the disposal of the Government of Burma, with effect from the date on which he assumes charge of his civil duties.

The services of Major S. D. Billimoria, I.M.S., were placed temporarily at the disposal of the Government of the Punjab, with effect from the 17th January, 1927.

Major H. Hingston, M.D., I.M.S., did general duty at the Presidency General Hospital, Calcutta, from the afternoon of the 12th to the afternoon of the 27th January, 1927.

Major N. C. Kapur, I.M.S., is appointed to do general duty at the Medical College Hospitals, with effect from the forenoon of the 24th January, 1927, until further orders.

The services of the undermentioned Indian Medical Service officers are placed permanently at the disposal of the Government of Bombay, with effect from the dates shown against their names:—

Major E. S. Phipson—28th November, 1925.
Major A. H. Harty—20th September, 1926.
Captain J. M. Shah—2nd May, 1926.

LEAVE.

Lieutenant-Colonel H. B. Steen, I.M.S., officiating Professor of Clinical and Operative Surgery, Medical College, Calcutta, is granted leave from the 1st April 1927 (or from the date on which the leave is availed of), to the 29th September, 1927.

Major E. H. V. Hodge, I.M.S., Surgeon to His Excellency the Governor of Bengal, is allowed combined leave for one year, with effect from the 30th March, 1927, or from any subsequent date on which he may avail himself of the leave.

PROMOTIONS.

Lieutenant-Colonel to be Colonel.

Lieutenant-Colonel W. O's. Murphy, M.B., *vice* Colonel J. H. McDonald, M.B., K.H.P., retired. Dated 1st November, 1926.

The undermentioned Lieutenant-Colonels of the Indian Medical Service to be Brevet-Colonels, with effect from the 1st January, 1927:—

A. Spitteler, O.B.E.
J. Norman Walker.

Majors to be Lieutenant-Colonels.

Pheroze Kharsedji Tarapore. Dated 2nd February, 1927.
Dwarkanath Dhamaji Kamat. Dated 2nd February, 1927.
William Edward Rees Williams, O.B.E., M.B. Dated 2nd February, 1927.
Alexander Frederick Babonau, C.I.E., O.B.E., M.B. Dated 2nd February, 1927.
Sorabji Jamasji Bhathena. Dated 2nd February, 1927.
G. E. Malcomson, M.D. Dated 20th January, 1927.
H. W. Acton. Dated 27th January, 1927.
V. B. Green-Armytage, M.D. Dated 27th January, 1927.
A. N. Dickson, M.C., M.D. Dated 27th January, 1927.
A. J. H. Russell, C.B.E., M.D. Dated 27th January, 1927.
R. E. Wright, M.D. Dated 27th January, 1927.
D. H. Rai, M.C., M.D. Dated 27th January, 1927.
F. A. Barker, O.B.E., M.B. Dated 27th January, 1927.
A. N. Thomas, D.S.O., M.B. Dated 27th January, 1927.

Captains to be Majors.

H. Aung Khin, M.B., F.R.C.S.E. Dated 19th November, 1926.
M. A. Singh, M.B. Dated 27th December, 1926.
Frank Oppenheimer. Dated 30th July, 1926.
Ulick Joseph Bourke. Dated 21st January, 1927.
Sundar Das Sondhi, M.C., M.B. Dated 20th January, 1927.

Lieutenant to be Captain.

T. J. Davidson, M.B. Dated 6th June, 1926.

RESIGNATIONS.

Subject to His Majesty's approval, Captain M. F. D. Graham, M.D., I.M.S., is permitted to resign the service with effect from the 18th February, 1927.

RETIREMENT.

Subject to His Majesty's approval, Lieutenant-Colonel M. N. Chaudhuri, I.M.S., is permitted to retire from the service, with effect from the 27th January, 1927.

NOTES.

RYTHMIN, CARNRICK & CO.

THE increase in intestinal and hepatic disorders in recent years has been marked. Particularly in sedentary walks of life is there need for the physician's services in maintaining a normal hepato-intestinal condition.

Bile salts, as is well known, are the only substances which directly stimulate bile production. They also increase peristalsis. Bile salts are to-day recognised by pharmacologists as the only true stimulant to excretion of bile. All other drugs, such as calomel, podophyllum, some of which have been highly regarded for these effects, have been found upon careful scientific examination to be devoid of such action on the liver.

The peristaltic principle in gastric mucosa was demonstrated by Zuelzer, and was later shown to be present in large quantities in the spleen. The hormones secretin and gastrin shown by Bayliss and Starling and by Edkin to increase the pancreatic, gastric, biliary and intestinal secretions are contained in the desiccated substance of the duodenal and gastric mucosæ.

Rythmin (G. W. Carnrick Co. 421 Canal Street, New York City), which combines these therapeutic principles therefore is a true cholagogue and in addition to its laxative effects, maintains a normal flow of bile through the bile ducts, thus offering an effective therapeutic agent in the treatment of biliary insufficiency, gall-stones and obstructive jaundice.

H. R. NAPP'S PREPARATIONS.

THREE preparations by the firm of H. R. Napp, 3 & 4 Clements Inn, Kingsway, London are of interest. The first is "Normocol"—an intestinal evacuant, non-injurious, non-habit-forming, and pleasant to take. It consists of sugar-coated granules of desiccated plant mucus of the Bassorin group, which possesses an enormous power of absorbing water, swelling to a soft mass enormously greater than its original bulk. Thus it is claimed that in contact with water a teaspoonful of Normacol will swell to a volume equal to that of 9 lbs. of cauliflower, 7 lbs. of apples, or 16 lbs. of bread. The result of its administration is to produce a regular mechanical evacuation free from griping, and of considerable bulk. The dose is one heaped teaspoonful, taken with a draught of water, tea, or coffee once or twice a day after the principal meals. The preparation is one which is especially suitable for children.

"Mastan" is a bacterial antigen, made from strains of streptococci, staphylococci, Pfeiffer's bacillus and tuberculosis bacilli, put up in capillary tubes similar to those used for vaccinial lymph, and intended to be used by a scarification and rubbing in technique similar to that employed in vaccination. It is of value in the treatment of acute and chronic inflammations, synovitis. erysipelas, acne, neuritis, and furunculosis. The reactions are as a rule considerable, but are followed by rapid improvement of symptoms.

"Neo-reargon" is a chemical compound of silver and anthraquinone glucosides, containing about 14 per cent. of silver in ionised form. Both silver salts and anthraquinone glucosides have a destructive action on the gonococcus, whilst the latter penetrate into tissues well and have an analgesic action. The preparation is intended for administration by the urethra in cases of gonorrhœa. The liquid is injected and the patient directed to retain it in the urethra as long as possible. A 5 per cent. solution may be used for abortive treatment of gonorrhœa, 5 or 6 injections being given on the first day, and 3 or 4 a day for the next few days. For an established anterior urethritis a 2½ per cent. solution may be injected four times a day; for posterior urethritis injections of a 1 to 2 per cent. solution may be practised 2 to 3 times daily, or posterior urethral irrigation with a 1|4 per cent. solution. The solution must be made up in distilled water, as chlorides affect the compound and precipitate the silver in it. The analgesic properties of the compound render it especially suitable for acute cases accompanied by much pain. A brochure issued by the firm gives full and detailed instructions for its use in different types of cases.

THE RAI SAHEB SHAMBHU DAYAL SAHEB GOLD MEDAL.

WE have received the notice given below with regard to the award of this gold medal for 1927 from the Director of Public Health, United Provinces. It should be noted that entries are limited to those residing in the United Provinces only, and that the essay should be written in Hindi.

1. A gold medal called the "Rai Saheb Shambhu Dayal Saheb Gold Medal" will be presented for the best prize essay on a public health subject to be announced each year.
2. The subject for the essay for 1927 is "Inculcation of health habits among the inhabitants of urban areas."
3. The competition will be open to the general public of the United Provinces.
4. The essay is to be written in Hindi and should not exceed 3,000 words in length.
5. The essay should reach the Director of Public Health, U. P., Lucknow, by May 31, 1927.
6. The name and address of the competitors must be distinctly written on each essay submitted, and the envelope should have the words "Prize Essay" in the top left hand corner.
7. The Director of Public Health, U. P. shall judge the merit of the essay and his decision with regard to the award of the medal shall be final.
8. No correspondence will be entered into on the subject to competition.
9. No essay will be returned.

CHEMISTS' EXHIBITION, LONDON.

THE 32nd Chemists' Exhibition will take place on May 9th to 13th, 1927, at the Holland Park Hall, London, W. The Exhibition was established in 1896, and has filled a very important need to the practising pharmacist in enabling him to see all the goods he sells and apparatus, etc., he uses in his profession under one roof. The management is always delighted to welcome visitors from the Dominions and Colonies, and such gentlemen will be admitted on presentation of business card. The exhibition is organised by the *British & Colonial Pharmacist*, and is strictly confined to the Trade. The General Strike in England in May last caused the abandonment of the 1926 Exhibition and the amount of support already guaranteed assures that the 1927 event will be much the largest and most important yet held.

Publishers' Notice.

SCIENTIFIC Articles and Notes of interest to the profession in India are solicited. Contributors of Original Articles will receive 25 reprints *gratis*, if asked for at the time of submitting their manuscripts.

Communications on Editorial Matters, Articles, Letters and Books for Review should be addressed to THE EDITOR, *The Indian Medical Gazette*, c|o The Calcutta School of Tropical Medicine, Central Avenue, Calcutta.

Communications for the Publishers relating to Subscriptions, Advertisements, and Reprints should be addressed to THE PUBLISHERS, Messrs. Thacker, Spink & Co., P. O. Box 54, Calcutta.

Annual Subscription to "The Indian Medical Gazette," Rs. 16 including postage, in India. Rs. 18 including postage, abroad.

Papers and articles forwarded for publication are understood to be offered to *The Indian Medical Gazette* alone, and any breach of this rule will be followed by non-publication.

The Editors of *The Indian Medical Gazette* cannot advise correspondents with regard to prescriptions, diagnosis, etc., nor can they recommend individual practitioners by name, as any such action would constitute a breach of professional etiquette.

Original Articles.

A PLEA FOR A THOROUGH INVESTIGATION OF THE FILARIASIS PROBLEM.*

By SIR FRANK CONNOR, D.S.O., F.R.C.S. (Eng.),
LIEUTENANT-COLONEL, I.M.S.,
Professor of Surgery, Calcutta Medical College.

ENORMOUS INCIDENCE OF FILARIASIS.

THE surgical onlooker in the tropics, who has few opportunities for laboratory work and fewer opportunities for field work, becomes more and more impressed with the magnitude of the filariasis problem and its many ramifications. It also appears to him, rightly or wrongly, that no concerted effort is being made to deal with it.

Filariasis may be compared to an evil genius, whose stakes are human lives, and whose dice are heavily loaded. Surely we must do something to destroy this genius, or at least to unload the dice.

The incidence of filarial disease is at present incalculable. Its ravages have been traced throughout vast areas of the tropical and subtropical world; parts of S. Europe, India, China, the Pacific Islands, Australia, the West Indies, and many other tropical lands are known to be infected. Clinically one soon discovers that it is broader and longer than its allotted span, or to change the metaphor, that it too often calls in accomplices, more malevolent than itself, to work its wicked will. The streptococcus is one of the worst of these.

The pathological manifestations of *F. bancrofti* are too well known to need any description here, but the very fact of our familiarity with these manifestations seems to deceive us into thinking that we really understand the mode of their production.

MANY GAPS IN OUR KNOWLEDGE.

The discoveries of Manson, and the work of his successors have placed on a sure basis the mosquito phase of *F. bancrofti* and many facts in connection with the life-history and pathology of the parasite in the human host. There are still, however, very serious gaps in our knowledge.

(*i*) Experimental evidence is needed to tell us exactly what happens after the metamorphosed microfilariæ enter the human host from the mosquito. They are next found as sexually mature filariæ coiled together in the lymphatic vessels and glands, the females laden with embryos which are poured into the blood stream. We know very little of the intermediate stages.

(*ii*) Information is also badly needed as to how the adult filariæ destroy and obstruct the lymphatic vessels and glands; is it a mechanical process, or by the help of a toxin?

(*iii*) With regard to the microfilariæ, we know that their presence in the blood in countless millions is not necessarily associated with any clinical symptoms. Are they capable of producing pathological changes under other conditions? The reasons for their habit of nocturnal or diurnal periodicity are also not at all well understood.

(*iv*) When we come to the pathological manifestations of filariasis, questions are even more easy to ask and more difficult to answer. What is filarial fever? Is it caused directly by filarial activities or by a secondary factor, such as streptococcal infection? What is the periodicity of filarial fever due to?

(*v*) Then with regard to the varying types of lymphatic obstruction, the solid elephantiasis, the soft lymph scrotum, the solid œdema which may come in one night, the small localised patches of œdema, the lymphatic and gland varices, etc., the details of all of these require elucidation. Some cases are definitely associated with streptococcal or erysipelatoid attacks, others are not.

(*vi*) Hydroceles in the tropics are very puzzling as to their ætiology. Many are obviously associated with filarial infection. The commonest type of hydrocele in Bengal, however, occurs in cases without any filarial manifestations. The globus major of the epididymis is dusky red in early cases and of a firm consistency; in more chronic cases, the process has spread downwards towards the globus minor, the consistency is still harder and the digital fossa is completely obliterated by an adhesive process. What is the pathology of these cases?

The above-mentioned are a few of the puzzles which filariasis provides and which still require unravelling.

SCATTERED NATURE OF PRESENT INQUIRIES.

As far as India is concerned, there seems to be no organised attempt in being, or in prospect, to deal with a disease which is known to be causing misery to some millions of its inhabitants. Sporadic efforts are being made, it is true, but surely this vast question is worthy of more liberal treatment.

Leprosy is a disease of much smaller incidence, causing less misery and a much lower mortality. Yet leprosy claims more abundant funds and highly skilled workers. These efforts are most praiseworthy in their attempt to prevent and cure a most disgusting disease, but they leave one wondering the more at the comparative neglect of a disease of much greater importance.

NEED FOR SOMETHING ON THE LINES OF A "FILARIASIS COMMISSION."

Past researches in India and in other places have taught us that filariasis cannot be studied in the laboratory alone. A mosquito survey is essential together with local investigation of the causes that are responsible for the sharp

* Being a paper read at the *Indian Science Congress*, Lahore, in January, 1927.

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

differences which occur in the filarial incidence and clinical manifestations of the disease in neighbouring villages or districts.

It is not likely that individual efforts will settle these problems, and prophylactic and curative measures cannot be evolved unless a proper understanding is arrived at as regards the ætiology and pathology of the infective process.

It was in India that the problem of malaria was solved. The problem of filariasis has already been partly solved by Manson, but as regards prophylaxis and cure we are still very much in the dark. It would be very fitting if this work could be completed in India, for filariasis is to tropical surgery what malaria is to tropical medicine. The Indian Science Congress could do much by adding the weight of its authority to a demand for a "Filariasis Commission," or some such organised effort to unravel these hidden aspects of filariasis.

CLINICAL EVIDENCE FAVOURS THE VIEW THAT EARLY TREATMENT IS LIKELY TO BE VERY SUCCESSFUL.

The treatment of filariasis has been very disappointing, and this is not to be wondered at when one considers our ignorance regarding its detailed pathology. It is quite possible that early infections could be effectively controlled, before the parent worms had, as it were, dug themselves in. Unfortunately early diagnosis is not yet possible.

Tartar emetic and many other well-known vermicides have been tried without much success. The author has, however, been much impressed with the fact that the persistent use of "soamin" hypodermically or intravenously seldom fails to give some measure of relief with regard to the many and very distressing symptoms. One has to speak with great caution when discussing such a subject, as the symptomatic vagaries of filariasis are of common knowledge. The disappearance of microfilariæ from the blood is also not a test of any great value. It would appear that in *early cases* soamin does do something to alleviate symptoms. If this is true, other arsenical derivatives may well be more efficacious. One is most impressed by the testimony of young Indian doctors who have suddenly discovered themselves to be the victims of filariasis by the appearance of some acute symptom for the first time. These can be regarded as fairly reliable witnesses. Several cases of this sort have come to the notice of the authorities. One was a young doctor, who worked with his own microscope. A sharp attack of fever associated with swellings of the inguinal lymph glands aroused his suspicions and he at once examined a smear of his night blood, to find it full of microfilariæ. Intravenous injections of soamin were at once started with the following dosage: bi-weekly doses, two of gr. 1, two of gr. 2, and two of gr. 3, i.e., 12 gr. in all. After a week's interval, this course was repeated and great improvement has followed. A most important advance in the treatment of filariasis would be the discovery of a test by means of which an early diagnosis of infection could be established. Drugs which are ordinarily of no avail might well be more efficacious when pitted against young filariæ, which are lying loosely in the tissues, not yet protected by a resistant fibrous tissue capsule.

Mortality from filariasis, though seldom direct, is probably enormous.

The devious ways in which filarial affections manifest themselves can only be appreciated by a long residence in the tropics. Cellulitis, gangrene, erysipelatous attacks, abscesses, acute exacerbations of fever, chylous extravasations, are only a few of the ills which are well known to be filarial in origin and which may kill outright, or wear away a patient. It is by its innumerable complications, therefore, that the mortality of filariasis is to be estimated and there can be no doubt whatever that the total mortality is very considerable.

Clinical evidence proves that the sick-rate involved, and therefore the industrial loss, is very great.

One has only to realise the clinical history of a case of elephantiasis of the legs or scrotum, or of recurring chylous extravasation, to appreciate the truth of this statement. In many cases chronic invalidism results, in others wage-earning capacity is much lowered by recurring exacerbations of a febrile or inflammatory nature. It is very difficult to estimate the numbers who are thus afflicted, but in endemic zones many thousands must be involved.

Has the time not arrived for organised and co-ordinated enquiry on the proper scale into the filariasis problem of India?

A NEW SPECIES OF ANOPHELINE *A. PSEUDOJAMESI* COMMON IN BENGAL.

By C. STRICKLAND, M.A., B.C.,
Professor of Medical Entomology, School of Tropical Medicine and Hygiene, Calcutta;
and
K. L. CHOWDHURY, M.B., D.P.H.,
Malariologist
(*Indian Research Fund Association*, 1926–27).

(*MS. received for publication, 17th March*, 1927.)

DURING an anopheline survey of Bengal, financed by the Indian Research Fund Association, which has been carried out during the recent financial year (1926-27), a species in the larval state was encountered, which was at first, in the absence of actual specimens or of any more complete description than that given by Stephens and Christophers (1902) or by James and Liston (1911), thought to be *pulcherrimus*. This idea, however, became suspect when a specimen hatched out and the imago presented itself as *jamesi*, and was diagnosed as such in spite of the larva in the case being very unlike that of *jamesi* (see Figs. 1 and 2).

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

When in the course of the survey, however, very many more specimens (from all over Bengal) were obtained and the larva was invariably* distinct in several respects from *jamesi*, the matter was studied afresh and it was then found that the adult was also constantly distinct from *jamesi* (Fig. 3); in one male specimen the genitalia being examined and noted to be different from this species (Figs. 4 and 5). It was on these grounds considered to be new, and we have named it *pseudojamesi*.

In our study of the species we came to learn that the larva is peculiarly and uniformly dark in coloration, a deep sage-green, and of a delicate and fine structure; which points enabled one to distinguish them by the naked eye, e.g., when mounted serially with other species on a glass slide for microscopic examination. Moreover, they required special care as compared with well-known species to ensure their hatching out.

With regard to the microscopic structure of the larva and adult, we will now give as complete an account as possible, adding a note on the habitat of the larva.

STRUCTURE OF THE LARVA.

(See Figs. 1 and 2.)

General Characters. All chitinous structures uniformly pigmented dark greenish-grey.

Head:—antenna: short spines all over, and darkly pigmented throughout its whole length.

clypeal hairs:—(See Fig. 1.) *antero-internal:* very long, thin, straight, pigmented dark grey. Slight fraying usually noticed, but in some specimens simple hairs have been observed. *antero-external:* short, straight, and distinctly frayed; about half the length of the antero-internal. *Posterior:* short, thin, straight, simple, and situated in a line with the antero-internal.

frontal hairs: six well-developed long branched hairs.

occipital hairs: both simple.

Thorax: antero-thoracic hairs are of the normal type; they carry a pair of rudimentary palmate hairs.

Abdomen:—palmate hairs on segments 1—2 rudimentary; on segments 3—7 well-developed; leaflets with short filaments about a quarter of the blade in length. (See Fig. 2.) *dorsal plaques* are uniformly pigmented dark grey and oval in shape.

Fig. 1.

Fig. 2.

DIAGNOSIS FROM CERTAIN OTHER LARVÆ.

	A. jamesi.	*A. maculipalpis.*	*A. pseudojamesi.*
(*a*) Clypeal hairs.			
Antero-internal	thickly frayed	distinctly frayed	very fine fraying (sometimes).
Antero-external	heavily-branched; 2/3 of ant.-int. in length	thick fraying, 2/3 of ant.-int. in length	thin fraying, ½ the length of ant.-int.
Posterior	branched	simple, relatively long	simple, short and thin.
(*b*) Palmate hair on abdominal segts.	well-developed on 2—7 segts.	well-developed on 1—7 segts.	well-developed on 3—7 segts.
Filament	long and sharp	short and blunt	short and sharp.

* No annectant forms have at any time been discovered.

THE LARVAL HABITATS IN BENGAL.

The species has been captured in the following places, which illustrate its type of breeding place:—

	Districts.	*Place.*	*Breeding places.*
(1)	Malda	Rohanpur	River Purna Babamar (a dying river with much floating vegetation).
(2)	Khulna	Khulna (town)	temporary pool of water.
(3)	Mymensingh	Bidyagunj	borrow-pit for huts.
(4)	Nadia	Badkulla	large tank.
(5)	"	Kanchrapara	the Kulia Bhil.
(6)	Burdwan	Memari	long railway cutting (borrow-pit).
(7)	"	Katwa	borrow-pit for railway line.
(8)	Faridpur	Pachooria	long railway-cutting.
(9)	Noakhali	Chaumuhani	long railway-cutting.

THE ADULT STRUCTURE (Figs. 3, 4 and 5).

Both the male and female have their legs with spotted tibiæ and femora and the hind legs have the 3 terminal segments *plus* the articulation on the second inter-tarsal joint continuously white. The first inter-tarsal joint is also banded (see Fig. 3).

Fig. 3.

In all other respects except in the male genitalia the species is similar to *A. jamesi*.

Fig. 4.

Fig. 5.

Male genitalia:—(as in Fig. 4): *claspette* spines 5, disposed as in the figure, with a

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

horizontal line of 3 and a fourth spine immediately below forming part of the cluster. The 4th spine is longer and stouter than any of the first three. There is a 5th slightly below and to the outside of the 4th. The inner portion of the lower half of the ventral surface of the clasper is beset with 6—8 long straight hairs arising from papillæ. Accessory hairs are numerous and very small. About 6—8 medium size accessory hairs below the cluster of spines.

Harpago unilobular with ventral club. Apical hair a little longer than the club. An accessory hair with thick chitinous base external to the apical hair and about ¾ of its length. Internally about half-a-dozen long thin hairs with basal papillæ; minute hairs cover the inner portion of the organ.

Theca more than half the length of the clasper, with thick chitinised margin and rather strongly chitinised leaflets.

Anal lobe reaches slightly below middle of clasper.

The 5th figure is *A. jamesi* for comparison and it shews the distinctive points from *pseudojamesi*. It is taken from Christophers (1916).

PATHOGENICITY.

Of course nothing can be said regarding its pathogenicity, but in our 6 months survey we took 101 of the species as compared with 316 *aconitus* and 220 *culicifacies*.

A SHORT REPORT ON SOME THERAPEUTIC INVESTIGATIONS CARRIED OUT AT THE RANCHI EUROPEAN MENTAL HOSPITAL.

By OWEN BERKELEY-HILL,
LIEUTENANT-COLONEL, I.M.S.

DURING the past year my four assistants have been kind enough to investigate for me certain forms of treatment for psychotic disorders which have been brought to our notice. The results of the investigations are as follows:—

(1) *Treatment by induction of aseptic meningitis:*

In October, 1923, Dr. Carrol published in the *New York Medical Journal* a paper entitled: "Aseptic meningitis in combating the dementia præcox problem." Further investigation of this form of treatment was later carried out by Drs. Carroll, Barr, Barry and Matzke. The results of their observations were published in the *American Journal of Psychiatry* in April, 1925. As these investigators remark, it has often been observed that improvement sometimes occurs in dementia præcox cases during the leucocytosis of infectious processes. Some years ago, Lundvall of Sweden noted that dementia præcox patients who were losing ground exhibited a leucopenia, whereas when they were improving they shewed a leucocytosis. The final conclusions reached by these four American observers may be summarised as follows: (1) The injection of sterile inactivated horse serum into the spinal canal produces an aseptic meningitis with marked physical reactions. (2) That the mental condition of 66 per cent. of cases of dementia præcox so treated shows improvement which has lasted from 2 to 11 months, several enjoying remissions. Insight is often gained. (3) That a fundamental principle not yet fully determined is involved, the further investigation of which may throw much light on the etiology of dementia præcox.

At my request, Dr. J. N. J. Pacheco undertook to apply this form of treatment to six selected cases of dementia præcox. The routine followed was: A day prior to the beginning of the treatment, the patient was admitted into the infirmary ward and put to bed on a milk diet. Calomel (½ gr.) was given in the evening and a saline purge in the following morning. It was decided to inject 20 c.c. of horse serum. A sufficient quantity of blood was drawn from the vein of a horse and allowed to stand in test tubes. The supernatant serum was drawn off. As much difficulty was experienced in getting enough blood for repeated injections, we tried the horse serum manufactured by Messrs. Burroughs Wellcome & Co. Unfortunately no reaction could be got with this serum, a fact we attributed to the possible inclusion of preservatives in the serum. Finally, a supply of fresh inactivated serum was got from Kasauli. As a rule 20 c.c. were injected into the spinal canal through the third lumbar interspace. To render the injection painless, 1 c.c. of aposthesine was injected locally. A spinal needle was then introduced and 20 c.c. of cerebro-spinal fluid withdrawn and an equal quantity of serum injected at the same rate. The patient was then put to bed and the lower end of the bed raised about a foot off the ground to allow quicker circulation to the cerebral meninges. The temperature, pulse and respiration were noted every hour. The nurse was given instructions to report any symptoms of vomiting, purging or collapse. The patient was kept on a milk diet. No other treatment was given. In all six cases were thus treated. On the whole the results were disappointing as compared with those obtained by other workers who have claimed 50 per cent of successes. The cases were as follows:—

CC-0. In Public Domain. Gurukul Kangri Collection, Haridwar

Digitized by Arya Samaj Foundation Chennai and eGangotri

Case 1.—S. C., Anglo-Indian male, aged 25. Negativistic. Unclean and slovenly. Temporal and spatial disorientation. Occasionally sings or shouts in Bengali. On 16th July, 1926, injected 19 c.c. Reaction nil. Temperature rose to 99°F. on the 17th. After that the temperature fell to normal and remained so. On the 24th July, patient was again injected with 17 c.c. Temperature rose to 101°F. in four hours. The day following the temperature fell to 99°F. After that the temperature was normal and remained so. During the period of mild pyrexia the patient seemed brighter and complained of severe headache. He replied readily and with attention to questions. On 20th October, he was again injected with 20 c.c. The temperature rose to 100°F. and remained so until 22nd. After that date it was normal. There was no marked leucocytosis beyond a relative eosinophilia of 8.8%. On 4th November the patient was again injected with 20 c.c. The temperature rose to 100°F. and remained so for two days. On the 16th November the patient was again injected with 20 c.c. The temperature rose to 101°F. on that day and then remained normal. No improvement took place in the patient's mental condition.

Case 2.—C. M., Anglo-Indian, male, aged 24. Negativistic. Completely disorientated in time and space. Injected on 9th July with 18 c.c. serum. Temperature stood at 100°F. for two days. Afterwards normal. No leucocytosis. Eosinophilia 4.1%. No change in mental condition.

Case 3.—A. A. K., Anglo-Indian, male, aged 25. Untidy and unkempt. Disorientated in time and space. Morose and sullen. Constantly spitting about and scribbling on the walls and floors. Injected on 21st October, with 19 c.c. serum. After eight hours temperature rose to 100°F. Temperature normal on the third day. Again injected on 4th November with 20 c.c. Temperature 102°F. on the following day. Normal on the 26th. Patient has stopped spitting but otherwise there is no change in his mental condition.

Case 4.—E. R., Anglo-Indian, female, aged 35. Negativistic, apathetic and silent. On 8th July injected with 9 c.c. fresh horse serum. Temperature rose to 103°F. four hours after the injection. Severe headache and vomiting. Very restless. Asked for refreshment. Kept groaning and shouting. Temperature fell gradually to normal on the 11th July. Again injected with 17 c.c. on the 16th July. Temperature rose to 103°F. in four hours. Temperature fell gradually and was normal on 19th July. Eosinophilia 11%. No change in mental condition. This patient has gradually grown feebler and feebler, both mentally and physically.

Case 5.—F. J. C., Anglo-Indian, female, aged 36. Noisy, abusive, dirty and loquacious. Injected on 3rd December with 10 c.c. serum. Temperature rose to 99°F. after eight hours. Temperature was 100.6°F. on the following day. Fell to normal on the 6th December. On 10th December patient was again injected with 20 c.c. serum. In four hours the temperature rose to 102.4°F. The temperature remained at this level until the 12th December. On the 15th the temperature was normal. During the febrile stage the patient was very quiet. Eosinophilia, 0.4%. No change in the mental condition.

Case 6.—H. B., European female, aged 40. Noisy, abusive and dirty. On 10th December she was injected with 20 c.c. This patient would not lie down under any circumstances so there was no reaction. On the following day the temperature was 99°F. and on the next day it was normal. No change in the mental condition of the patient.

In spite of the very disappointing results with these six cases, I am glad to be able to state that Dr. Pacheco intends to carry the investigation further and to publish a report when he has collected more data.

(2) *The intensive use of bromides:*

It seems that Ulrich of Zurich was the first to employ bromide to the point of marked intoxication in the treatment of mental disorder. He claims to have treated successfully 10 cases of melancholia by giving his patients huge doses of bromide. Later Klaesi employed a somewhat similar line of treatment, using somnifen and luminal. In January 1926, Dr. William W. Wright of the Utica State Hospital, published a paper in the *American Journal of Psychiatry* in which he suggested a new method of treating functional psychoses by bromide intoxication. Dr. Wright summarises his results as follows:—
